Acknowledgments

I would like to welcome and acknowledge my wife, Ingrid Tulloch, as co-author for this second edition of the Microsoft Encyclopedia of Networking. Ingrid is a skilled researcher whose research has contributed extensively to both this edition and the previous one, and I thank Microsoft Press for their willingness to recognize her contribution to this project by adding her name next to mine.

My thanks also to the terrific team at Microsoft Press, including Juliana Aldous (Acquisitions Editor) and Maureen Zimmerman (Project Editor), and at nSight, especially Susan McClung (Project Manager), Ari Globerman and John Panzarella (Technical Editors), and Joseph Gustaitis (Copy Editor).

Thanks to David L. Rogelberg and Neil Salkind, my agents at Studio B Literary Agency, and to all the other wonderful people there.

Finally, thanks to my many readers and friends whose suggestions and comments regarding the first edition have been incorporated into this new edition and have helped make it what it is—the BEST networking encyclopedia EVER!

Preface to the Second Edition

Welcome to the second edition of the popular *Microsoft Encyclopedia of Networking*, the premier resource for network architects, system engineers, network administrators, and IT professionals. The purpose of this Preface is to briefly describe the new and exciting changes found in this new edition, which can be summarized by the simple word *more*. Specifically, in this new edition of this encyclopedia you'll find

- **More coverage of key networking concepts and technologies.** We've added hundreds of new articles covering the latest networking technologies, including wireless networking, 3G cellular communication, broadband Internet access, LAN-host integration, network management, network security, network troubleshooting, disaster recovery, enterprise applications, P2P technologies, virus protection, carriers and service providers, and e-business standards and technologies. In addition, coverage of basic networking standards, protocols, architectures, and technologies has been enhanced and extended throughout the work by including new articles on cabling standards, routing protocols, security protocols, signal encoding methods, encryption schemes, component architectures, WAN services, multilayer switching, tape formats, multiplexing methods, remote access, terminal-based computing, Voice over IP, and the organization and operation of the Internet. And that's only scratching the surface!
- **More depth of coverage in key articles.** Essential technologies and standards, such as 802.11b wireless, ATM, Bluetooth, cellular communications, Classless Interdomain Routing, DSL, DNS, Ethernet, frame relay, Gigabit Ethernet, GSM, and ISDN, are covered in much more detail than they were in the first edition. In addition to a brief definition and overview of the subject, longer articles are

frequently divided into a number of different subsections for greater clarity and more logical treatment of the subject. Headings for these subsections include Overview, History, Types, Uses, Comparison, Architecture, Implementation, Examples, Advantages and Disadvantages, Issues, Notes, and For More Information.

- **More coverage of key platforms.** Coverage of the Microsoft Windows NT platform and applications has been de-emphasized in this edition to make room for coverage of Windows 2000, Windows XP, and Microsoft's new .NET framework. In addition, increased coverage of popular UNIX platforms and open-source technologies such as Linux and Apache has been included. Overall, this new edition is less Microsoft-centric than the first edition, and instead focuses more on general networking concepts, technologies, and services with fair coverage of competing platforms from many different vendors.
- **Up-to-date coverage of standards, products, and services.** The networking world has changed considerably since the first edition of this encyclopedia came out, with the Application Services Provider marketplace exploding and then imploding, home-grown intranets evolving into powerful Enterprise Knowledge Portals, Token Ring and FDDI going the way of the dinosaur, 3G expectations being replaced by 2.5G realities, XML standards proliferating but failing to displace EDI in the marketplace, and new vendors and service providers appearing, merging, and going bankrupt faster than fruit flies can multiply. As a result of these changes, every article in this work has been thoroughly revised and updated to include the latest and most accurate information possible. In addition, many articles include two special subsections: Marketplace,

which provides a snapshot of vendors and products available at the time of writing; and Prospects, which offers our best prediction of how technologies and services will evolve over the next few years.

- **Expanded cross-references.** The list of cross-references at the end of each article has been greatly expanded to enhance the usefulness of this work as the essential reference guide for networking professionals of all levels, ranging from students pursuing their MCSE to senior network architects with years of field experience.
- **Revised introduction.** The introduction to the book has been revised and updated, and the section called History of Networking has been brought up to date with developments that have taken place since the first edition.

In conclusion, we hope you enjoy using this new edition of the *Microsoft Encyclopedia of Networking* as much as we have enjoyed writing it!

Introduction

Welcome to the second edition of the *Microsoft Encyclopedia of Networking*, a general survey of computer networking concepts, technologies, and services. This work is intended to be a comprehensive, accurate, and up-to-date resource for students, system engineers, network administrators, IT (information technology) implementers, and computing professionals from all walks of life. Before we outline this work's scope and coverage, we will ask a simple question that is surprisingly difficult to answer: what is networking?

What Is Networking?

In the simplest sense, networking means connecting computers so that they can share files, printers, applications, and other computer-related resources. The advantages of networking computers are fairly obvious:

- Users can save their important files and documents on a file server. This is more secure than storing them on workstations because a file server can be backed up in a single operation.
- Users can share a network printer, which costs much less than having a locally attached printer for each user's computer.
- Users can share groupware applications running on application servers, which enables users to share documents, send messages, and collaborate directly.
- The job of administering and securing a company's computer resources is simplified since they are concentrated on a few centralized servers.

The above definition of networking focuses on the basic goals of networking computers together: increased manageability, security, cost-effectiveness, and efficiency over non-networked systems. However, we

could also focus our discussion on the different *types* of networks, including

- Personal area networks (PANs), once the stuff of science fiction but rapidly becoming a reality as the mobile knowledge workers of today carry around an array of cell phones, Personal Digital Assistants (PDAs), pagers, and other small devices
- Local area networks (LANs), which can range from a few desktop workstations in a Small Office/Home Office (SOHO) to several thousand workstations and dozens of servers deployed throughout dozens of buildings on a university campus or in an industrial park
- Metropolitan area networks (MANs), which span an urban area and are generally run by telcos and other service providers to provide companies with high-speed connectivity between branch offices and with the Internet
- Wide area networks (WANs), which might take the form of a company's head office linked to a few branch offices or an enterprise spanning several continents with hundreds of offices and subsidiaries
- The Internet, the world's largest network and the "network of networks"

On the other hand, we could also focus on the different networking *architectures* in which these various types of networks can be implemented, including

- Peer-to-peer networking, which might be implemented in a workgroup consisting of computers running Microsoft Windows 98 or Windows 2000 Professional
- Server-based networking, which might be based on the domain model of Windows NT, the domain trees and forests of Active Directory directory

service in Windows 2000, or another architecture such as Novell Directory Services (NDS) for Novell NetWare

- Terminal-based networking, which might be the traditional host-based mainframe environment; the UNIX X Windows environment; the terminal services of Windows NT Server 4 Enterprise Edition; Windows 2000 Advanced Server; or Citrix MetaFrame

Or we could look at the various networking *technologies* used to implement these architectures, including

- LAN technologies such as Ethernet, Token Ring, Fiber Distributed Data Interface (FDDI), Fast Ethernet, Gigabit Ethernet (GbE), and the emerging 10G Ethernet (10GbE)
- WAN technologies such as Integrated Services Digital Network (ISDN), T-carrier leased lines, X.25, frame relay, Asynchronous Transfer Mode (ATM), Synchronous Optical Network (SONET), Digital Subscriber Line (DSL), and metropolitan Ethernet
- Wireless communication technologies such as the wireless LAN (WAN) standards 802.11a and 802.11b, and the consumer wireless technologies HomeRF and Bluetooth
- Cellular communication systems such as Time Division Multiple Access (TDMA), Code Division Multiple Access (CDMA), Global System for Mobile Communications (GSM), and the emerging 3G cellular communication standards

In addition, we could consider the *hardware* used to implement these different networking technologies, including

- LAN devices such as repeaters, concentrators, bridges, hubs, Ethernet switches, and routers
- WAN devices such as modems, ISDN terminal adapters, Channel Service Units (CSUs), Data Service Units (DSUs), packet assembler/disassemblers (PADs), frame relay access devices (FRADs), multiplexers (MUXes), and inverse multiplexers (IMUXes)

- Equipment for organizing, protecting, and troubleshooting LAN and WAN hardware, such as racks, cabinets, surge protectors, line conditioners, uninterruptible power supplies (UPSs), KVM switches, and cable testers
- Cabling technologies such as coaxial cabling, twinax cabling, twisted-pair cabling, fiber-optic cabling, and associated equipment such as connectors, patch panels, wall plates, and splitters
- Unguided media technologies such as infrared communication, wireless cellular networking, and satellite networking, along with their associated hardware
- Data storage technologies such as redundant array of independent disks (RAID), network-attached storage (NAS), and storage area networks (SANs) along with their associated hardware, plus various enabling technologies, including Small Computer System Interface (SCSI) and Fibre Channel

Or we could talk about various technologies that *enhance the reliability, scalability, security, and manageability* of computer networks, including

- Technologies for implementing network security, including firewalls, proxy servers, and virtual private networking (VPN), and such devices as smart cards and firewall appliances
- Technologies for increasing availability and reliability of access to network resources, such as clustering, caching, load balancing, Layer 7 switching, and terminal services
- Network management technologies such as Simple Network Management Protocol (SNMP), Remote Network Monitoring (RMON), Web-Based Enterprise Management (WBEM), Common Information Model (CIM), and Windows Management Instrumentation (WMI)

Returning to a more general level, networking can also be thought of as the various *standards* that underlie the different networking technologies and hardware mentioned above, including

- The Open Systems Interconnection (OSI) networking model from the International Organization for Standardization (ISO)
- The G-series, H-series, I-series, T-series, V-series, and X-series standards from the International Telecommunication Union (ITU)
- Project 802 of the Institute of Electrical and Electronics Engineers (IEEE)
- The Requests for Comment (RFC) series from the Internet Engineering Task Force (IETF)
- Various standards developed by the World Wide Web Consortium (W3C), the Frame Relay Forum, the ATM Forum, the Gigabit Ethernet Alliance, and other standards organizations
- Electronic messaging protocols such as X.400, Simple Mail Transfer Protocol (SMTP), Post Office Protocol version 3 (POP3), and Internet Mail Access Protocol version 4 (IMAPv4)
- Directory protocols such as X.500's Directory Access Protocol (DAP) and the Lightweight Directory Access Protocol (LDAP)
- Security protocols such as Password Authentication Protocol (PAP), Challenge Handshake Authentication Protocol (CHAP), Windows NT LAN Manager (NTLM) Authentication, Kerberos, IP Security Protocol (IPsec), Secure Sockets Layer (SSL), and public key cryptography standards and protocols
- Serial interface standards such as RS-232, RS-422/423, RS-485, V.35, and X.21

Networking *protocols* deserve special attention in any definition of the word *networking*. These protocols include:

- LAN protocols such as NetBEUI, Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX), Transmission Control Protocol/Internet Protocol (TCP/IP), and AppleTalk
- WAN protocols such as Serial Line Internet Protocol (SLIP), Point-to-Point Protocol (PPP), Point-to-Point Tunneling Protocol (PPTP), and Layer 2 Tunneling Protocol (L2TP)
- Protocols developed within mainframe computing environments, such as Systems Network Architecture (SNA), Advanced Program-to-Program Communications (APPC), Synchronous Data Link Control (SDLC), and High-level Data Link Control (HDLC)
- Routing protocols such as the Routing Information Protocol (RIP), Interior Gateway Routing Protocol (IGRP), Open Shortest Path First (OSPF) Protocol, and Border Gateway Protocol (BGP)
- Internet protocols such as the Hypertext Transfer Protocol (HTTP), File Transfer Protocol (FTP), Network News Transfer Protocol (NNTP), and the Domain Name System (DNS)

We could dig still deeper and discuss the *fundamental engineering concepts* that underlie the various networking technologies and services previously discussed, including

- Impedance, attenuation, shielding, near-end crosstalk (NEXT), and other characteristics of cabling and other transmission systems
- Signals and how they can be multiplexed using time-division, frequency-division, statistical, and other multiplexing techniques
- Transmission parameters including bandwidth, throughput, latency, jabber, jitter, backbone, handshaking, hop, dead spots, dark fiber, and late collisions
- Balanced vs. unbalanced signals, baseband vs. broadband transmission, data communications equipment (DCE) vs. data terminal equipment (DTE), circuit switching vs. packet switching, connection-oriented vs. connectionless communication, unicast vs. multicast and broadcast, point-to-point vs. multipoint links, direct sequencing vs. frequency hopping methods, and switched virtual circuit (SVC) vs. permanent virtual circuit (PVC)

We could also talk about the different types of *providers* of networking services, including

- Internet service providers (ISPs), application service providers (ASPs), and integrated communications providers (ICPs)
- Telcos or local exchange carriers (LECs), including both Regional Bell Operating Companies (RBOCs) and competitive local exchange carriers (CLECs), that offer such popular broadband services as Asymmetric Digital Subscriber Line (ADSL) and High-bit-level Digital Subscriber Line (HDSL) through their central office (CO) and local loop connection
- Inter-exchange carriers (IXCs) that provide popular WAN services such as dedicated leased lines and frame relay for the enterprise (large companies)
- Local loop alternatives including cable modems, fixed wireless, and satellite networking companies

We could also list the various *software technologies* vendors have developed that make computer networking both useful and possible, including

- Network operating systems such as Windows, Novell NetWare, UNIX, and Linux
- Specialized operating systems such as Cisco Systems' Internetwork Operating System (IOS), which runs on Cisco routers, and the variant of IOS used on Cisco's Catalyst line of Ethernet switches
- Directory systems such as Microsoft Corporation's domain-based Active Directory, Novell Directory Services (NDS), and various implementations of X.500 and LDAP directory systems
- File systems such as NTFS file system (NTFS) on Windows platforms and distributed file systems such as the Network File System (NFS) developed by Sun Microsystems for the UNIX platform
- Programming languages and architectures for developing distributed computing applications, such as the C/C++ and Java languages, Microsoft's ActiveX and Sun's Jini technologies, component technologies such as Distributed Component Object Model (DCOM) and COM+, interprocess

communication (IPC) technologies such as Remote Procedure Calls (RPCs) and named pipes, and Internet standards such as the popular Hypertext Markup Language (HTML) and the Extensible Markup Language (XML) family of standards

- Tools for integrating networking technologies in heterogeneous *environments*, such as Gateway Services for NetWare (GSNW), Services for Macintosh, Services for UNIX on the Windows 2000 platforms, and Microsoft Host Integration Server, all of which provide connectivity with mainframe systems

On an even deeper level, we could focus on the various *administration tools* for managing networking hardware, platforms, services and protocols, including

- The Microsoft Management Console (MMC) and its various snap-ins in the Windows 2000 and Windows .NET Server platforms
- The various ways routers and network appliances can be administered using Telnet, terminal programs, and the universal Web browser interface
- Popular TCP/IP command-line utilities such as arp, ping, ipconfig, traceroute, netstat, nbtstat, finger, and nslookup
- Platform-specific command-line utilities such as various Windows commands used for automating common administration tasks
- Cross-platform scripting languages that can be used for system and network administration, including JavaScript, VBScript, and Perl

We could also look at various *enterprise applications* widely used in networked environments, including

- Enterprise Resource Planning (ERP) and Customer Relationship Management (CRM) platforms
- Enterprise Information Portal (EIP) and Enterprise Knowledge Portal (EKP) platforms
- The Microsoft .NET Enterprise Server family of applications that includes Microsoft Application Center Server, BizTalk Server, Commerce Server,

Exchange Server, Host Integration Server, Internet Security and Acceleration Server, Mobile Information Server, and SQL Server

I think that you can see by now that we could go on and on, slowly unpeeling our answer to the question “What is networking?” like the many layers of an onion. And it is pretty obvious by now that there is more to networking than just hubs and cables! In fact, the field of computer networking today is almost overwhelming in its breadth and complexity, and one could spend a lifetime studying only one small aspect of the subject.

This has not always been the case. Let’s take a look now at how the field of computer networking has reached the amazing point where it is today.

The History of Networking

Because networking is such a broad and complex subject, no single event represents its point of origin. However, we can arbitrarily decide on the 1960s as the formative period for the field, since that is when the computer began to affect significantly the lives of ordinary individuals and the day-to-day operation of both business and government.

1960s

In the 1960s computer networking was essentially synonymous with mainframe computing, and the distinction between local and wide area networks did not yet exist. Mainframes were typically “networked” to a series of dumb terminals with serial connections running on RS-232 or some other electrical interface. If a terminal in one city needed to connect with a mainframe in another city, a 300-baud long-haul modem would use the existing analog Public Switched Telephone Network (PSTN) to form the connection. The technology was primitive indeed, but it was an exciting time nevertheless. I remember taking a computer science class in high school toward the end of the decade, and having to take my box of punch cards down to the mainframe terminal at the university and wait in line for the output from the line printer. Alas, poor Fortran, I knew thee well!

To continue the story, the quality and reliability of the PSTN increased significantly in 1962 with the introduction of pulse code modulation (PCM), which converted analog voice signals into digital sequences of bits. A consequent development was the first commercial touch-tone phone, which was introduced in 1962. Before long, digital phone technology became the norm, and DS-0 (Digital Signal Zero) was chosen as the basic 64-kilobit-per-second (Kbps) channel upon which the entire hierarchy of the digital telephone system was built. A later development was a device called a channel bank, which took 24 separate DS-0 channels and combined them together using time-division multiplexing (TDM) into a single 1.544-Mbps channel called DS-1 or T1. (In Europe, 30 DS-0 channels were combined to make E1.) When the backbone of the Bell telephone system finally became fully digital years later, the transmission characteristics improved significantly for both voice and data transmission due to higher quality and less noise associated with Integrated Services Digital Network (ISDN) digital lines, though local loops have remained analog in many places. But that is getting a little ahead of the story.

The first communication satellite, Telstar, was launched in 1962. This technology did not immediately affect the networking world because of the high latency of satellite links compared to undersea cable communications, but it eventually surpassed transoceanic underwater telephone cables (which were first deployed in 1965 and could carry 130 simultaneous conversations) in carrying capacity. In fact, early in 1960 scientists at Bell Laboratories transmitted a communication signal coast-to-coast across the United States by bouncing it off the moon! By 1965 popular commercial communication satellites such as Early Bird were being widely deployed and used.

As an interesting aside, in 1961 the Bell system proposed a new telecommunications service called TELPAK, which it claimed would lead to an “electronic highway” for communication, but it never pursued the idea. Could this have been an early portent of the “information superhighway” of the mid-1990s?

The year 1969 witnessed an event whose full significance was not realized until more than two decades

later: namely, the development of the ARPANET packet-switching network. ARPANET was a project of the U.S. Department of Defense's Advanced Research Projects Agency (ARPA), which became DARPA in 1972. Similar efforts were underway in France and the United Kingdom, but it was the U.S. project that eventually evolved into the present-day Internet. (France's MINTEL packet-switching system, which was based on the X.25 protocol and which aimed to bring data networking into every home, did take off in 1984 when the French government started giving away MINTEL terminals; by the early 1990s, more than 20 percent of the country's population was using it.) The original ARPANET network connected computers at Stanford University, the University of California at Los Angeles (UCLA), the University of California at Santa Barbara (UCSB), and the University of Utah, with the first node being installed at UCLA's Network Measurement Center. A year later, Harvard University, the Massachusetts Institute of Technology (MIT), and a few other prominent institutions were added to the network, but few of those involved could imagine that this technical experiment would someday profoundly affect modern society and the way we do business.

The year 1969 also saw the publication of the first Request For Comments (RFC) document, which specified the Network Control Protocol (NCP), the first transport protocol of ARPANET. The informal RFC process evolved into the primary means of directing the evolution of the Internet and is still used today.

That same year, Bell Laboratories developed the UNIX operating system, a multitasking, multiuser network operating system (NOS) that became popular in academic computing environments in the 1970s. A typical UNIX system in 1974 was a PDP-11 minicomputer with dumb terminals attached. In a configuration with 768 kilobytes (KB) of magnetic core memory and a couple of 200-megabyte (MB) hard disks, the cost of such a system would have been around \$40,000. I remember working in those days on a PDP-11 in the cyclotron lab of my university's physics department, feeding in bits of punched tape and watching lights flash. It was an incredible experience.

Many important standards for computer systems also evolved during the 1960s. In 1962, IBM introduced the first 8-bit character encoding system, called Extended Binary-Coded Decimal Interchange Code (EBCDIC). A year later the competing American Standard Code for Information Interchange (ASCII) was introduced. ASCII ultimately won out over EBCDIC even though EBCDIC was 8-bit and ASCII was only 7-bit. The American National Standards Institute (ANSI) formally standardized ASCII in 1968. ASCII was first used in serial transmission between mainframe hosts and dumb terminals in mainframe computing environments, but it was eventually extended to all areas of computer and networking technologies.

Other developments in the 1960s included the development in 1964 of IBM's powerful System/360 mainframe computing environment, which was widely implemented in government, university, and corporate computing centers. In 1966, IBM introduced the first disk storage system, which employed 50 metal platters, each of which was 2 feet (0.6 meter) wide and had a storage capacity of 5 MB. IBM created the first floppy disk in 1967. In 1969, Intel Corporation released a RAM chip that stored 1 KB of information, which at the time was an amazing feat of engineering.

1970s

Although the 1960s were the decade of the mainframe, the 1970s gave birth to Ethernet, which today is by far the most popular LAN technology. Ethernet was born in 1973 in Xerox Corporation's research lab in Palo Alto, California. (An earlier experimental network called ALOHAnet was developed in 1970 at the University of Hawaii.) The original Xerox networking system was known as X-wire and worked at 2.94 Mbps. X-wire was experimental and was not used commercially, although a number of Xerox Palo Alto workstations used for word processing were networked together in the White House using X-wire during the Carter administration. In 1979, Digital Equipment Corporation (DEC), Intel, and Xerox formed the DIX consortium and developed the specification for standard 10-Mbps Ethernet, or thicknet, which was published in 1980. This standard was revised and additional features were added in the following decade.

The conversion of the backbone of the Bell telephone system to digital circuitry continued during the 1970s and included the deployment in 1974 of the first digital data service (DDS) circuits (then called the Dataphone Digital Service). DDS formed the basis of the later deployment of ISDN and T1 lines to customer premises, and AT&T installed its first digital switch in 1976.

In wide area networking, a new telecommunications service called X.25 was deployed toward the end of the decade. This new system was packet-switched, in contrast to the circuit-switched PSTN, and later evolved into public X.25 networks such as GTE's Telenet Public Packet Distribution Network (PDN), which later became SprintNet. X.25 was widely deployed in Europe, where it still maintains a large installed base, especially for communications in the banking and financial industry.

In 1970 the Federal Communications Commission (FCC) announced the regulation of the fledgling cable television industry. Cable TV remained primarily a broadcast technology for delivering entertainment to residential homes until the mid-1990s, when technologies began to be developed to enable it to carry broadband services to residential subscribers. Cable modems now compete strongly with Digital Subscriber Line (DSL) as the main two forms of broadband Internet access technologies.

Despite all these technological advances, however, telecommunications services in the 1970s remained unintegrated, with voice, data, and entertainment carried on different media. Voice was carried by telephone, which was still analog at the customer premises; entertainment was broadcast using radio and television technologies; and data was usually carried over RS-232 or Binary Synchronous Communication (BSC) serial connections between dumb terminals and mainframes (or, for remote terminals, long-haul modem connections over analog telephone lines).

The 1970s were also notable for the growth of ARPANET, which grew throughout the decade as additional hosts were added at various universities and government institutions. By 1971 the network had 19 nodes, mostly consisting of a mix of PDP-8, PDP-11,

IBM S/360, DEC-10, Honeywell, and other mainframe and minicomputer systems linked together. The initial design of ARPANET called for a maximum of 265 nodes, which seemed like a distant target in the early 1970s. The initial protocol used on this network was NCP, but this was replaced in 1982 by the more powerful TCP/IP protocol suite. In 1975 the administration of ARPANET came under the authority of the Defense Communications Agency.

ARPANET protocols and technologies continued to evolve using the informal RFC process developed in 1969. In 1972 the Telnet protocol was defined in RFC 318, followed by FTP in 1973 (RFC 454). ARPANET became an international network in 1973 when nodes were added at the University College of London in the United Kingdom and at the Royal Radar Establishment in Norway. ARPANET even established an experimental wireless packet-switching radio service in 1977, which two years later became the Packet Radio Network (PRNET).

Meanwhile, in 1974 the first specification for the Transmission Control Protocol (TCP) was published. Progress on the TCP/IP protocols continued through several iterations until the basic TCP/IP architecture was formalized in 1978, but it was not until 1983 that ARPANET started using TCP/IP instead of NCP as its primary networking protocol.

The year 1977 also saw the development of UNIX to UNIX Copy (UUCP), a protocol and tool for sending messages and transferring files on UNIX-based networks. An early version of the USENET news system using UUCP was developed in 1979. (The Network News Transfer Protocol [NNTP] came much later, in 1987.)

In 1979 the first commercial cellular phone system began operation in Japan. This system was analog in nature, used the 800-MHz and 900-MHz frequency bands, and was based on a concept developed in 1947 at Bell Laboratories.

An important standard to emerge in the 1970s was the public-key cryptography scheme developed in 1976 by Whitfield Diffie and Martin Hellman. This scheme

underlies the Secure Sockets Layer (SSL) protocol developed by Netscape Communications, which is still the predominant approach for ensuring privacy and integrity of financial and other transactions over the World Wide Web (WWW). Without SSL, popular e-business sites such as Amazon and eBay would have a hard time attracting customers!

Among other miscellaneous developments during this decade, in 1970 IBM researchers invented the relational database, a set of conceptual technologies that has become the foundation of today's distributed application environments. In 1971, IBM demonstrated the first speech recognition technologies—which have since led to those annoying automated call handling systems found in customer service centers! IBM also developed the concept of the virtual machine in 1972 and created the first sealed disk drive (the Winchester) in 1973. In 1974, IBM introduced the Systems Networking Architecture (SNA) for networking its mainframe computing environment. In 1971, Intel released its first microprocessor, a 4-bit processor called the 4004 that ran at a clock speed of 108 kilohertz (kHz), a snail's pace by modern standards but a major development at the time. Another significant event was the launching of the online service CompuServe in 1979, which led to the development of the first online communities.

The first personal computer, the Altair, went on the market as a kit in 1975. The Altair was based on the Intel 8080, an 8-bit processor, and came with 256 bytes of memory, toggle switches, and light-emitting diode (LED) lights. Although the Altair was basically for hobbyists, the Apple II from Apple Computer, which was introduced in 1977, was much more. A typical Apple II system, which was based on the Motorola 6502 8-bit processor, had 4 KB of RAM, a keyboard, a motherboard with expansion slots, built-in BASIC in ROM, and color graphics. The Apple II quickly became the standard desktop system in schools and other educational institutions. A physics classroom I taught in had one all the way into the early 1990s (limited budget!). However, it was not until the introduction of the IBM Personal Computer (PC) in 1981 that the full potential of personal computers began to be realized, especially in businesses.

In 1975, Bill Gates and Paul Allen licensed their BASIC computer programming language to MITS, the Altair's manufacturer. BASIC was the first computer language specifically written for a personal computer. Gates and Allen coined the name "Microsoft" for their business partnership, and they officially registered it as a trademark the following year. Microsoft Corporation went on to license BASIC to other personal computing platforms such as the Commodore PET and the TRS-80. I loved BASIC in those early days, and I still do!

1980s

In the 1980s the growth of client/server LAN architectures continued while that of mainframe computing environments declined. The advent of the IBM PC in 1981 and the standardization and cloning of this architecture led to an explosion of PC-based LANs in businesses and corporations around the world, particularly with the release of the IBM PC AT hardware platform in 1984. The number of PCs in use grew from 2 million in 1981 to 65 million in 1991. Novell, which appeared on the scene in 1983, soon became a major player in file and print servers for LANs with its Novell NetWare platform.

However, the biggest development in the area of LAN networking in the 1980s was the continued evolution and standardization of Ethernet. While the DIX consortium worked on Ethernet standards in the late 1970s, the IEEE with its Project 802 initiative tried working toward a single unified LAN standard. When it became clear that this goal was impossible, Project 802 was divided into a number of separate working groups, with 802.3 focusing on Ethernet, 802.4 on Token Bus, and 802.5 on Token Ring technologies and standards. The work of the 802.3 group resulted in the first Ethernet standard, called 10Base5 or thicknet, which was almost identical to the version developed by DIX. 10Base5 was called thicknet because it used thick coaxial cable, and in 1985 the 802.3 standard was extended to include 10Base2 using thin coaxial cable, commonly called thinnet.

Through most of the 1980s, coaxial cable was the main form of cabling used for implementing Ethernet. A company called SynOptics Communications, however, developed a product called LattisNet that was designed

for transmitting 10-Mbps Ethernet over twisted-pair wiring using a star-wired topology that was connected to a central hub or repeater. This wiring was cheaper than coaxial cable and was similar to the wiring used in residential and business telephone wiring systems. LattisNet was such a commercial success that in 1990 the 802.3 committee approved a new standard called 10BaseT for Ethernet that ran over twisted-pair wiring. 10BaseT soon superseded the coaxial forms of Ethernet because of its ease of installation and because its hierarchical star-wired topology was a good match for the architectural topology of multistory buildings.

In other Ethernet developments, fiber-optic cabling, first developed in the early 1970s by Corning, found its first commercial networking application in Ethernet networking in 1984. (The technology itself was standardized as 10BaseFL in the early 1990s.) In 1988 the first fiber-optic transatlantic undersea cable was laid and greatly increased the capacity of transatlantic communication systems.

Ethernet bridges became available in 1984 from DEC and were used both to connect separate Ethernet LANs to make large networks and to reduce traffic bottlenecks on overloaded networks by splitting them into separate segments. Routers could be used for similar purposes, but bridges generally offered better price and performance, as well as less complexity, during the 1980s. Again, market developments preceded standards, as the IEEE 802.1D Bridge Standard, which was initiated in 1987, was not standardized until 1990.

In the UNIX arena, the development of the Network File System (NFS) by Sun Microsystems in 1985 resulted in a proliferation of diskless UNIX workstations having built-in Ethernet interfaces. This development helped drive the demand for Ethernet and accelerated the evolution of Ethernet bridging technologies into today's switched networks. By 1985 the rapidly increasing numbers of UNIX hosts and LANs connected to the ARPANET began to transform it from what had been mainly a network of mainframe and minicomputer systems into something like what it is today. The first UNIX implementation of TCP/IP came in v4.2 of Berkeley's BSD UNIX, from which other vendors such as Sun Microsys-

tems quickly ported their versions of TCP/IP. Although PC-based LANs rapidly grew in popularity in business and corporate settings during the 1980s, UNIX continued to dominate in academic and professional high-end computing environments as the mainframe environment declined.

IBM introduced its Token Ring networking technology in 1985 as an alternative LAN technology to Ethernet. IBM had submitted its technology to the IEEE in 1982 and the 802.5 committee standardized it in 1984. IBM soon supported the integration of Token Ring with its existing SNA networking services and protocols for IBM mainframe computing environments. The initial Token Ring specifications delivered data at 1 Mbps and 4 Mbps, but it dropped the 1-Mbps version in 1989 when it introduced a newer 16-Mbps version. Interestingly, no formal IEEE specification exists for 16-Mbps Token Ring—vendors simply adopted IBM's technology for the product. Efforts were made to develop high-speed Token Ring, but these have finally been abandoned and today Ethernet reigns supreme.

Also in the field of local area networking, in 1982 the American National Standards Institute (ANSI) began standardizing the specifications for Fiber Distributed Data Interface (FDDI). FDDI was designed to be a high-speed (100 Mbps) fiber-optic networking technology for LAN backbones on campuses and industrial parks. The final FDDI specification was completed in 1988, and deployment in campus LAN backbones grew during the late 1980s and the early 1990s. But today FDDI is considered legacy technology and has been superseded in most places by Fast Ethernet and Gigabit Ethernet (GbE).

In 1983 the ISO developed an abstract seven-layer model for networking called the Open Systems Interconnection (OSI) reference model. Although some commercial networking products were developed based on OSI protocols, the standard never really took off, primarily because of the predominance of TCP/IP. Other standards from the ISO and ITU that emerged in the 1980s included the X.400 electronic messaging standards and the X.500 directory recommendations, both of which held sway for a while but have now largely

been superseded—X.400 by the Internet's Simple Mail Transfer Protocol (SMTP) and X.500 by Lightweight Directory Access Protocol (LDAP).

A major event in the telecommunications/WAN field in 1984 was the divestiture of AT&T as the result of the seven-year antitrust suit brought against AT&T by the U.S. Justice Department. AT&T's 22 Bell operating companies were formed into 7 new RBOCs (only 4 are left today). This meant the end of the old Bell telephone system, but these RBOCs soon formed the Bellcore telecommunications research establishment to replace the defunct Bell Laboratories. The United States was then divided into Local Access and Transport Areas (LATAs), with intra-LATA communication handled by local exchange carriers (the Bell Operating Companies or BOCs) and inter-LATA communication handled by inter-exchange carriers (IXCs) such as AT&T, MCI, and Sprint Corporation.

The result of the breakup was increased competition, which led to new WAN technologies and generally lower costs. One of the first effects was the offering of T1 services to subscribers in 1984. Until then, this technology had been used only for backbone circuits for long-distance communication. New hardware devices were offered to take advantage of the increased bandwidth, especially high-speed T1 multiplexers, or muxes, that could combine voice and data in a single communication stream. The year 1984 also saw the development of digital Private Branch Exchange (PBX) systems by AT&T, bringing new levels of power and flexibility to corporate subscribers.

The Signaling System #7 (SS7) digital signaling system was deployed within the PSTN in the 1980s, first in Sweden and later in the United States. SS7 made new telephony services available to subscribers, such as caller ID, call blocking, and automatic callback.

The first trials of ISDN, a fully digital telephony technology that runs on existing copper local loop lines, began in Japan in 1983 and in the United States in 1987. All major metropolitan areas in the United States have since been upgraded to make ISDN available to those who want it,

but ISDN has not caught on in the United States as a WAN technology as much as it has in Europe.

The 1980s also saw the standardization of SONET technology, a high-speed physical layer (PHY) fiber-optic networking technology developed from time-division multiplexing (TDM) digital telephone system technologies. Before the divestiture of AT&T in 1984, local telephone companies had to interface their own TDM-based digital telephone systems with proprietary TDM schemes of long-distance carriers, and incompatibilities created many problems. This provided the impetus for creating the SONET standard, which was finalized in 1989 through a series of Comité Consultatif International Télégraphique et Téléphonique (CCITT; anglicized as International Telegraph and Telephone Consultative Committee) standards known as G.707, G.608, and G.709. By the mid-1990s almost all long-distance telephone traffic in the United States used SONET on trunk lines as the physical interface.

The 1980s brought the first test implementations of Asynchronous Transfer Mode (ATM) high-speed cell-switching technologies, which could use SONET as the physical interface. Many concepts basic to ATM were developed in the early 1980s at the France-Telecom laboratory in Lannion, France, particularly the PRELUDE project, which demonstrated the feasibility of end-to-end ATM networks running at 62 Mbps. The CCITT standardized the 53-byte ATM cell format in 1988, and the new technology was given a further push with the creation of the ATM Forum in 1991. Since then, use of ATM has grown significantly in telecommunications provider networks and has become a high-speed backbone technology in many enterprise-level networks around the world. However, the vision of ATM on users' desktops has not been realized because of the emergence of cheaper Fast Ethernet and GbE LAN technologies and because of the complexity of ATM itself.

The convergence of voice, data, and broadcast information remained a distant vision throughout the 1980s and was even set back because of the proliferation of networking technologies, the competition between cable and broadcast television, and the slow adoption of residential ISDN. New services did appear, however,

especially in the area of commercial online services such as America Online (AOL), CompuServe, and Prodigy, which offered consumers e-mail, bulletin board systems (BBSs), and other services.

A significant milestone in the development of the Internet occurred in 1982 when the networking protocol of ARPANET was switched from NCP to TCP/IP. On January 1, 1983, NCP was turned off permanently—anyone who had not migrated to TCP/IP was out of luck. ARPANET, which connected several hundred systems, was split into two parts, ARPANET and MILNET.

The first international use of TCP/IP took place in 1984 at the Conseil Européen pour la Recherche Nucléaire (CERN), a physics research center located in Geneva, Switzerland. TCP/IP was designed to provide a way of networking different computing architectures in heterogeneous networking environments. Such a protocol was badly needed because of the proliferation of vendor-specific networking architectures in the preceding decade, including “homegrown” solutions developed at many government and educational institutions. TCP/IP made it possible to connect diverse architectures such as UNIX workstations, VMS minicomputers, and Cray supercomputers into a single operational network. TCP/IP soon superseded proprietary protocols such as Xerox Network Systems (XNS), ChaosNet, and DECnet. It has since become the de facto standard for internet-working all types of computing systems.

CERN was primarily a research center for high-energy particle physics, but it became an early European pioneer of TCP/IP and by 1990 was the largest subnetwork of the Internet in Europe. In 1989 a CERN researcher named Tim Berners-Lee developed the Hypertext Transfer Protocol (HTTP) that formed the basis of the World Wide Web (WWW). And all of this developed as a sidebar to the real research that was being done at CERN—slamming together protons and electrons at high speeds to see what fragments appeared!

Also important to the development of Internet technologies and protocols was the introduction of the Domain Name System (DNS) in 1984. At that time, ARPANET had more than 1000 nodes and trying to remember their

numerical IP addresses was a headache. DNS greatly simplified that process. Two other Internet protocols were introduced soon afterwards: NNTP was developed in 1987, and Internet Relay Chat (IRC) was developed in 1988.

Other systems paralleling ARPANET were developed in the early 1980s, including the research-oriented Computer Science Network (CSNET), and the Because It's Time Network (BITNET), which connected IBM mainframe computers throughout the educational community and provided e-mail services. Gateways were set up in 1983 to connect CSNET to ARPANET, and BITNET was similarly connected to ARPANET. In 1989, BITNET and CSNET merged into the Corporation for Research and Educational Networking (CREN).

In 1986 the National Science Foundation Network (NSFNET) was created. NSFNET networked the five national supercomputing centers together using dedicated 56-Kbps lines. The connection was soon seen as inadequate and was upgraded to 1.544-Mbps T1 lines in 1988. In 1987, NSF and Merit Networks agreed to jointly manage the NSFNET, which had effectively become the backbone of the emerging Internet. By 1989 the Internet had grown to more than 100,000 hosts, and the Internet Engineering Task Force (IETF) was officially created to administer its development. In 1990, NSFNET officially replaced the aging ARPANET and the modern Internet was born, with more than 20 countries connected.

Cisco Systems was one of the first companies in the 1980s to develop and market routers for Internet Protocol (IP) internetworks, a business that today is worth billions of dollars and is a foundation of the Internet. Hewlett-Packard was Cisco's first customer for its routers, which were originally called gateways.

In wireless telecommunications, analog cellular was implemented in Norway and Sweden in 1981. Systems were soon rolled out in France, Germany, and the United Kingdom. The first U.S. commercial cellular phone system, which was named the Advanced Mobile Phone Service (AMPS) and operated in the 800-MHz

frequency band, was introduced in 1983. By 1987 the United States had more than 1 million AMPS cellular subscribers, and higher-capacity digital cellular phone technologies were being developed. The Telecommunications Industry Association (TIA) soon developed specifications and standards for digital cellular communication technologies.

A landmark event that was largely responsible for the phenomenal growth in the PC industry (and hence the growth of the client/server model and local area networking) was the release of the first version of Microsoft's text-based, 16-bit MS-DOS operating system in 1981. Microsoft, which had become a privately held corporation with Bill Gates as president and chairman of the board and Paul Allen as executive vice president, licensed MS-DOS version 1 to IBM for its PC. MS-DOS continued to evolve and grow in power and usability until its final version, MS-DOS 6.22, which was released in 1993. (I still carry around a DOS boot disk wherever I go in case I need it—don't you?) Anyway, one year after the first version of MS-DOS was released in 1981, Microsoft had its own fully functional corporate network, the Microsoft Local Area Network (MILAN), which linked a DEC 206, two PDP-11/70s, a VAX 11/250, and a number of MC68000 machines running XENIX. This type of setup was typical of the heterogeneous computer networks that characterized the early 1980s.

In 1983, Microsoft unveiled its strategy to develop a new operating system called Windows with a graphical user interface (GUI). Version 1 of Windows, which shipped in 1985, used a system of tiled windows that allowed users to work with several applications simultaneously by switching between them. Version 2 was released in 1987 and supported overlapping windows as well as expanded memory.

Microsoft launched its SQL Server relational database server software for LANs in 1988. In its current version, SQL Server 2000 is an enterprise-class application that competes with other major database platforms such as Oracle and DB2. IBM and Microsoft jointly released their 32-bit OS/2 operating system in 1987 and released OS/2 1.1 with Presentation Manager a year later.

In miscellaneous developments, IBM researchers developed the Reduced Instruction Set Computing (RISC) processor architecture in 1980. Apple Computer introduced its Macintosh computing platform in 1984 (the successor of its Lisa system), which introduced a windows-based GUI that was the precursor to Windows. Apple also introduced the 3.5-inch floppy disk in 1984. Sony Corporation and Philips developed CD-ROM technology in 1985. (Recordable CD-R technologies were developed in 1991.) IBM released its AS/400 midrange computing system in 1988, which continues to be popular to this day.

1990s

The 1990s were an explosive decade in every aspect of networking, and we can only touch on a few highlights here. Ethernet continued to evolve as a LAN technology and began to eclipse competing technologies such as Token Ring and FDDI. In 1991, Kalpana Corporation began marketing a new form of bridge called a LAN switch, which dedicated the entire bandwidth of a LAN to a single port instead of sharing it among several ports. Later known as Ethernet switches or Layer 2 switches, these devices quickly found a niche in providing dedicated high-throughput links for connecting servers to network backbones. Layer 3 switches soon followed, eventually displacing traditional routers in most areas of enterprise networking except for WAN access. Layer 4 and higher switches are now popular in server farms for load balancing and fault tolerance purposes.

The rapid evolution of the PC computing platform and the rise of bandwidth-hungry applications created a need for something faster than 10-Mbps Ethernet, especially on network backbones. The first full-duplex Ethernet products, offering speeds of 20 Mbps, became available in 1992. In 1995 work began on a standard for full-duplex Ethernet; it was finalized in 1997. A more important development was Grand Junction Networks' commercial Ethernet bus, introduced in 1992, which functioned at 100 Mbps. Spurred by this advance, the 802.3 group produced the 802.3u 100BaseT Fast Ethernet standard for transmission of data at 100 Mbps over both twisted-pair copper wiring and fiber-optic cabling.

Although the jump from 10-Mbps to 100-Mbps Ethernet took almost 15 years, a year after the 100BaseT Fast Ethernet standard was released work began on a 1000-Mbps version of Ethernet popularly known as Gigabit Ethernet (GbE). Fast Ethernet was beginning to be deployed at the desktop, and this was putting enormous strain on the FDDI backbones that were deployed on many commercial and university campuses. FDDI also operated at 100 Mbps (or 200 Mbps if fault tolerance was discarded in favor of carrying traffic on the redundant ring), so a single Fast Ethernet desktop connection could theoretically saturate the capacity of the entire network backbone. Asynchronous Transfer Mode (ATM), a broadband cell-switching technology used primarily in telecommunication/WAN environments, was briefly considered as a possible successor to FDDI for backboning Ethernet networks together, and LAN emulation (LANE) was developed to carry LAN traffic such as Ethernet over ATM. However, ATM is much more complex than Ethernet, and a number of companies saw extending Ethernet speeds to 1000 Mbps as a way to provide network backbones with much greater capacity using technology that most network administrators were already familiar with. As a result, the 802 group called 802.3z developed a GbE standard called 1000BaseX, which it released in 1998. Today GbE is the norm for LAN backbones, and Fast Ethernet is becoming ubiquitous at the desktop level. Work is even underway on extending Ethernet technologies to 10 gigabits per second (Gbps). A competitor of GbE for high-speed collapsed backbone interconnects, called Fibre Channel, was conceived by an ANSI committee in 1988 but is used mainly for storage area networks (SANs).

The 1990s saw huge changes in the landscape of telecommunications providers and their services. “Convergence” became a major buzzword, signifying the combining of voice, data, and broadcast information into a single medium for delivery to businesses and consumers through broadband technologies such as metropolitan Ethernet, Digital Subscriber Line (DSL), and cable modem systems. The cable modem was introduced in 1996, and by the end of the decade broadband residential Internet access through cable television systems had

become a strong competitor with telephone-based systems such as Asymmetric Digital Subscriber Line (ADSL) and G.Lite, another variant of DSL.

Also in the 1990s, Voice over IP (VoIP) emerged as the latest “Holy Grail” of networking and communications and promised businesses huge savings by routing voice telephone traffic over existing IP networks. VoIP technology works, but the bugs are still being ironed out and deployments remain slow. Recent developments in VoIP standards, however, may help propel deployment of this technology in coming years.

The first public frame relay packet-switching services were offered in North America in 1992. Companies such as AT&T and Sprint installed a network of frame relay nodes across the United States in major cities, where corporate networks could connect to the service through their local telco. Frame relay began to eat significantly into the deployed base of more expensive dedicated leased lines such as the T1 or E1 lines that businesses used for their WAN solutions, resulting in lower prices for these leased lines and greater flexibility of services. In Europe frame relay has been deployed much more slowly, primarily because of the widespread deployment of packet-switching networks such as X.25.

The Telecommunications Act of 1996 was designed to spur competition in all aspects of the U.S. telecommunications market by allowing the RBOCs access to long-distance services and IXC access to the local loop. The result has been an explosion in technologies and services offered by new companies called competitive local exchange carriers (CLECs), with mergers and acquisitions changing the nature of the service provider landscape almost daily.

The 1990s saw a veritable explosion in the growth of the Internet and the development of Internet technologies. As mentioned earlier, ARPANET was replaced in 1990 by NSFNET, which by then was commonly called the Internet. At the beginning of the 1990s, the Internet’s backbone consisted of 1.544-Mbps T1 lines connecting various institutions, but in 1991 the process of upgrading these lines to 44.735-Mbps T3 circuits began. By the time the Internet Society (ISOC) was

chartered in 1992, the Internet had grown to an amazing 1 million hosts on almost 10,000 connected networks. In 1993 the NSF created Internet Network Information Center (InterNIC) as a governing body for DNS. In 1995 the NSF stopped sponsoring the Internet backbone and NSFNET went back to being a research and educational network. Internet traffic in the United States was routed through a series of interconnected commercial network providers.

The first commercial Internet service providers (ISPs) emerged in the early 1990s when the NSF removed its restrictions against commercial traffic on the NSFNET. Among these early ISPs were Performance Systems International (PSI), UUNET, MCI, and Sprintlink. (The first public dial-up ISP was actually The World, with the URL *www.world.std.com*.) In the mid-1990s, commercial online networks such as AOL, CompuServe, and Prodigy provided gateways to the Internet to subscribers. Later in the decade, Internet deployment grew exponentially, with personal Internet accounts proliferating by the tens of millions around the world, new technologies and services developing, and new paradigms evolving for the economy and business. It would take a whole book to talk about all the ways the Internet has changed our lives.

Many Internet technologies and protocols have come and gone quickly. Archie, an FTP search engine developed in 1990, is hardly used today. The WAIS protocol for indexing, storing, and retrieving full-text documents, which was developed in 1991, has been eclipsed by Web search technologies. Gopher, which was created in 1991, grew to a worldwide collection of interconnected file systems, but most Gopher servers have now been turned off. Veronica, the Gopher search tool developed in 1992, is obviously obsolete as well. Jughead later supplemented Veronica but has also become obsolete. (There never was a Betty.)

The most obvious success story among Internet protocols has been HTTP, which, with HTML and the system of URLs for addressing, has formed the basis of the Web. Tim Berners-Lee and his colleagues created the first Web server (whose fully qualified DNS name was *info.cern.ch*) and Web browser software using the NeXT computing platform that was developed by

Apple pioneer Steve Jobs. This software was ported to other platforms, and by the end of the decade more than 6 million registered Web servers were running, with the numbers growing rapidly.

Lynx, a text-based Web browser, was developed in 1992. Mosaic, the first graphical Web browser, was developed in 1993 for the UNIX X Windows platform by Marc Andreessen while he was a student at the National Center for Supercomputing Applications (NCSA). At that time, there were only about 50 known Web servers, and HTTP traffic amounted to only about 0.1 percent of the Internet's traffic. Andreessen left school to start Netscape Communications, which released its first version of Netscape Navigator in 1994. Microsoft Internet Explorer 2 for Windows 95 was released in 1995 and rapidly became Netscape Navigator's main competition. In 1995, Bill Gates announced Microsoft's wide-ranging commitment to support and enhance all aspects of Internet technologies through innovations in the Windows platform, including the popular Internet Explorer Web browser and the Internet Information Server (IIS) Web server platform of Windows NT. Another initiative in this direction was Microsoft's announcement in 1996 of its ActiveX technologies, a set of tools for active content such as animation and multimedia for the Internet and the PC.

In cellular communications technologies, the 1990s were clearly the "digital decade." The work of the TIA resulted in 1991 in the first standard for digital cellular communication, the TDMA Interim Standard 54 (IS-54). Digital cellular was badly needed because the analog cellular subscriber market in the United States had grown to 10 million subscribers in 1992 and 25 million subscribers in 1995. The first tests of this technology, based on Time Division Multiple Access (TDMA) technology, took place in Dallas, Texas, and in Sweden, and were a success. This standard was revised in 1994 as TDMA IS-136, which is commonly referred to as Digital Advanced Mobile Phone Service (D-AMPS).

Meanwhile, two competing digital cellular standards also appeared. The first was the CDMA IS-95 standard for CDMA cellular systems based on spread spectrum technologies, which was first proposed by

QUALCOMM in the late 1980s and was standardized by the TIA as IS-95 in 1993. Standards preceded implementation, however; it was not until 1996 that the first commercial CDMA cellular systems were rolled out.

The second system was the Global System for Mobile Communication (GSM) standard developed in Europe. (GSM originally stood for Groupe Spéciale Mobile.) GSM was first envisioned in the 1980s as part of the movement to unify the European economy, and the European Telecommunications Standards Institute (ETSI) determined the final air interface in 1987. Phase 1 of GSM deployment began in Europe in 1991. Since then, GSM has become the predominant system for cellular communication in over 60 countries in Europe, Asia, Australia, Africa, and South America, with over 135 mobile networks implemented. However, GSM implementation in the United States did not begin until 1995.

In the United States, the FCC began auctioning off portions of the 1900-MHz frequency band in 1994. Thus began the development of the higher-frequency Personal Communications System (PCS) cellular phone technologies, which were first commercially deployed in the United States in 1996.

Establishment of worldwide networking and communication standards continued apace in the 1990s. For example, in 1996 the Unicode character set, a character set that can represent any language of the world in 16-bit characters, was created, and it has since been adopted by all major operating system vendors.

In client/server networking, Novell in 1994 introduced Novell NetWare 4, which included the new Novell Directory Services (NDS), then called NetWare Directory Services. NDS offered a powerful tool for managing hierarchically organized systems of network file and print resources and for managing security elements such as users and groups. NetWare is now in version 6 and NDS is now called Novell eDirectory.

In other developments, the U.S. Air Force launched the twenty-fourth satellite of the Global Positioning System (GPS) constellation in 1994, making possible precise terrestrial positioning using handheld satellite communication systems. RealNetworks released its first

software in 1995, the same year that Sun Microsystems announced the Java programming language, which has grown in a few short years to rival C/C++ in popularity for developing distributed applications. Amazon.com was launched in 1995 and has become a colossus of cyberspace retailing in a few short years. Microsoft WebTV (now MSN TV), introduced in 1997, is beginning to make inroads into the residential Internet market.

Finally, the 1990s were, in a very real sense, the decade of Windows. No other technology has had as vast an impact on ordinary computer users as Windows, which brought to homes and workplaces the power of PC computing and the opportunity for client/server computer networking. Version 3 of Windows, which was released in 1990, brought dramatic increases in performance and ease of use over earlier versions, and Windows 3.1, released in 1992, quickly became the standard desktop operating system for both corporate and home users. Windows for Workgroups 3.1 quickly followed that same year. It integrated networking and workgroup functionality directly into the Windows operating system, allowing Windows users to use the corporate computer network for sending e-mail, scheduling meetings, sharing files and printers, and performing other collaborative tasks. In fact, it was Windows for Workgroups that brought the power of computer networks from the back room to users' desktops, allowing them to perform tasks previously possible only for network administrators.

In 1992, Microsoft released the first beta version of its new 32-bit network operating system, Windows NT. In 1993 came MS-DOS 6, as Microsoft continued to support users of text-based computing environments. That was also the year that Windows NT and Windows for Workgroups 3.11 (the final version of 16-bit Windows) were released. In 1995 came the long-awaited release of Windows 95, a fully integrated 32-bit desktop operating system designed to replace MS-DOS, Windows 3.1, and Windows for Workgroups 3.11 as the mainstream desktop operating system for personal computing. Following in 1996 was Windows NT 4, which included enhanced networking services and a new Windows 95-style user interface. Windows 95 was superseded by Windows 98 and later by Windows Millennium Edition (Me).

At the turn of the millennium came the long-anticipated successor to Windows NT, the Windows 2000 family of operating systems, which includes Windows 2000 Professional, Windows 2000 Server, Windows 2000 Advanced Server, and Windows 2000 Datacenter Server. The Windows family has now grown to encompass the full range of networking technologies, from embedded devices and Personal Digital Assistants (PDAs) to desktop and laptop computers to heavy-duty servers running the most advanced, powerful, scalable, business-critical, enterprise-class applications.

2000 and Beyond

It is early in the new millennium—where are we now and where are we going? The first question is relatively easy to answer:

- In the LAN field, Ethernet reigns supreme. Token Ring and FDDI are dead-end technologies, and ATM never caught on.
- Microsoft continues to be by far the dominant player on the desktop, and Windows XP has finally united the separate Windows 95, Windows 98, Windows Me, and Windows NT/2000 code streams into a single platform.
- In the enterprise (large companies), Windows NT and Windows 2000 have proved enormously popular as file, print, and application server platforms. Microsoft Exchange has eclipsed Lotus Notes as the dominant messaging platform, and Microsoft SQL Server is giving Oracle and DB2 a run for their money. IIS and Apache continue to fight it out for Web server supremacy, with each side claiming victory in different market segments. And Linux has established a niche for itself in the enterprise and continues to grow, mostly at the expense of Novell NetWare and UNIX platforms.
- Wireless networking using the 802.11b standard has exploded across the enterprise, but security continues to be a big concern for these networks, as “drive-by hackers” have shown with their laptops and BMWs. Data transmission over cellular communication systems is still incredibly slow in most areas, as 2G technologies are slowly superseded by 2.5G ones.

- Metropolitan Ethernet is the hottest WAN technology, letting companies access GbE services with plug-and-play simplicity. DSL is having trouble establishing itself as a viable enterprise option, mainly due to reliability issues. T1 prices are still ridiculously high, but not likely to change much due to consolidation in the service provider industry. And despite its lack of glamour, frame relay is going strong and still growing in the enterprise WAN.
- The Internet is now the blood and backbone of most businesses, but the number of Internet businesses that failed in the dot-com bust defies description. The Internet access market continues to consolidate, and broadband Internet access is now in the tens of millions of subscribers and rising rapidly. The “Big Three” online portals—MSN, Yahoo!, and AOL—now comprise an estimated 20 percent of all Internet traffic. Apart from eBay and Amazon, the number of truly great e-business success stories is amazingly small.
- B2B (business to business) e-business is on the rise but mostly hidden from view in the form of e-marketplaces for different corporate sectors. And XML, which promised to revolutionize e-business, is still a distant second in popularity to good old EDI.

We could say a lot more, but let’s briefly address the questions, “Where are we going? What might the rest of this decade hold as far as the growth and evolution of networking in all its forms?” Here are a few “hedged-bet” predictions for you to consider:

- Will we have 3G wireless broadband connectivity for everyone, everywhere, all the time? Or will most major cellular providers go bankrupt, throwing a monkey wrench into 3G deployments and putting them years behind schedule?
- Will 10 GbE provide users and companies with unparalleled amounts of bandwidth? Or will demand for bandwidth rise even more rapidly than new technologies can accommodate?

- Will P2P file sharing platforms finally bring the Internet (and most enterprises) to its knees? Or will Dense Wavelength Division Multiplexing (DWDM) be a knight in shining armor riding to the rescue?
- Will viruses, worms, Trojans, and other forms of “malware” continue to wreak havoc with the world economy? Or will a solution be found to this growing problem that does not involve disconnecting the network cable from your computer and locking it in your closet?
- Will Bluetooth usher in an exciting high-tech world of bionic humans carrying dozens of spontaneously networked devices all the time? Or will somebody finally invent a single device that does it all?
- And will rapid evolution in computer technologies, programming paradigms, networking architectures, and the Internet make us less human? Or more?

Let the reader decide—we will give you a partial answer when the third edition of this book comes out!

The Scope of This Encyclopedia

Now that you have an idea of what networking is all about and how it has evolved over the years, you probably realize that the scope of this encyclopedia is fairly broad. Most of the information found in this book falls into these categories:

- Information about networking concepts, technologies, standards, and hardware—including such things as Ethernet, Token Ring, bandwidth, latency, hubs, switches, OSI, and X.500.
- Information about the telecommunications industry, including WAN services such as frame relay, leased lines, and ATM. Also included is coverage of various wireless networking and cellular communication technologies.
- Information about the Internet and its standards, protocols, services, architecture, and implementation—including such things as HTTP, SMTP, Web servers, Web browsers, TCP/IP, BGP, and ASP.

- Information about popular software technologies used in developing network-aware solutions, including such platforms as Windows and Linux and such applications as Apache.

Also included in this book are numerous entries from areas that are usually considered peripheral to networking per se, including network-aware programming technologies such as Java and ActiveX and cryptography standards used in networking and communication, such as Advanced Encryption Standard (AES) and Public Key Cryptography Standards (PKCS). Networking professionals and students are likely to encounter many of these terms in their daily work and reading and will benefit from the inclusion of this material.

Finally, since this is the *Microsoft* Encyclopedia of Networking, there is extensive coverage of Microsoft platforms and products, including all versions of Windows, the .NET platform and .NET Server family, services such as TechNet and MSDN, the Microsoft Web site (one of the largest in the world), and Microsoft Corporation itself.

Who This Work Is For

This book will be an invaluable reference and learning tool for all levels of networking professionals, ranging from the seasoned professional with many years of hands-on experience to the individual pursuing an entry-level certification such as CompTIA's Network+. Individuals working toward the popular Microsoft Certified Systems Engineer (MCSE) will find the book particularly helpful in their endeavors.

Many other professionals will also find this work useful, including consultants, IT implementers, sales and marketing people, and the interested lay reader.

How This Work Is Organized

The articles in this work are listed in alphabetical order, of course, and their lengths range from a few paragraphs to several pages. Longer articles are organized for readability into a number of subsections, including Overview, History, Uses, Types, Comparison, Architecture,

Implementation, Examples, Advantages and Disadvantages, Marketplace, Issues, Prospects, and Notes. Figures are included in many articles to help explain key concepts. Most articles end with a section called See Also that has cross-references to related entries elsewhere in the encyclopedia. The section called For More Information provides URLs where you can find further information online.

An effort has been made to minimize technical jargon while maintaining technical accuracy. Coverage has included up-to-the-minute developments at the time of writing, but remember that networking technologies and products change rapidly. Microsoft Press provides short updates and corrections for its books at www.mspress.microsoft.com/support, but major updates in material will have to wait until the next edition.

Numbers and Symbols

1Base5

An obsolete 1 megabit per second (Mbps) local area network (LAN) networking technology.

Overview

1Base5 was actually developed after the 10Base5 Standard Ethernet specification was ratified but before the ratification of the 10BaseT standard. It was developed as an initial attempt to deploy computer networking over existing unshielded twisted-pair (UTP) cabling at a time when Ethernet was still based on coaxial cabling. The popular name for 1Base5 networking technologies was StarLAN because it was wired in a hierarchical star topology. When 10BaseT was ratified as an Institute of Electrical and Electronics Engineers (IEEE) standard in 1990, however, StarLAN and similar technologies quickly became obsolete and fell into disuse.

2B+D

Basic Rate Integrated Services Digital Network (ISDN) service, which uses two B channels and one D channel for signaling and communications.

See Also: Integrated Services Digital Network (ISDN)

2B1Q

Stands for Two Binary One Quaternary, a physical layer encoding mechanism for translating digital information into electrical signals, standardized by the American National Standards Institute (ANSI) and used in Integrated Services Digital Network (ISDN) networks. In 2B1Q, four electrical amplitude and polarity values are used to represent binary information.

2G

Stands for second generation and refers to widely deployed cellular communications systems such as Digital Advanced Mobile Phone Service (D-AMPS), Time Division Multiple Access (TDMA), Code Division Multiple Access (CDMA), Global System for Mobile Communications (GSM), and Personal Communication Services (PCS) systems.

See Also: 3G

2.5G

A label some vendors use to refer to several interim cellular communications systems currently being deployed as a prelude to full third-generation (3G) systems.

Overview

For many cellular systems, upgrading immediately from existing second-generation (2G) systems to full 3G functionality is costly and complex. Furthermore, some vendors question whether there is a need for the high (2 megabits per second) data rates promised by 3G and suggest that lower data rates in the hundreds of kilobits per second (Kbps) are more than sufficient for the majority of current applications. They cannot justify the enormous cost of an upgrade considering the insufficient demand for the type of interactive multimedia communications that 3G will support. Even 2.5G would be a significant leap forward from today's current 2G systems, where typical data rates are a mere 9.6, 14.4, or 19.2 Kbps.

As a result, some cellular service providers have opted to migrate from 2G to 3G in stages by first upgrading their existing Time Division Multiple Access (TDMA) and Code Division Multiple Access (CDMA) networks to interim technologies which offer much higher data transmission rates. These interim 2.5G systems include Enhanced Data Rates for Global Evolution (EDGE),

developed by Ericsson, and High Data Rate (HDR), developed by Qualcomm.

For example, some TDMA networks that can carry data at only 19.2 Kbps are being upgraded first to General Packet Radio System (GPRS) overlaid on Global System for Mobile Communications (GSM) to support data transmission at 144 Kbps, and from there to EDGE which supports transmission rates of 384 Kbps. In fact, GPRS is a natural upgrade path for GSM-based systems to support Wireless Application Protocol (WAP)-based data communications easily and inexpensively at speeds from 10s to 100s of Kbps.

Similarly, many CDMA systems carrying data at 14.4 Kbps are being upgraded to intermediate technologies such as HDR before being fully upgraded to Wideband CDMA (W-CDMA) with its 2 megabits-per-second (Mbps) data rate.

In addition to the increased data rates of 2.5G systems compared to 2G (about an order of magnitude faster), another advantage is that 2.5G systems utilize packet-switching technologies that are more efficient in the transmission of IP data over cellular systems as opposed to the circuit-switching technologies in use by existing 2G systems.

Notes

Most 2.5G systems are asymmetric in their transmission speeds, supporting faster downloads than uploads. In this way they bear some similarity to cable modems and Asymmetric Digital Subscriber Line (ADSL).

Some vendors market their 2.5G systems as 3G, but this is a misnomer because they fall short of complying with the International Telecommunication Union (ITU)'s IMT-2000 standard that defines 3G technologies and systems.

3G

Stands for third generation, an umbrella name for the latest generation of cellular phone networks capable of high-speed wireless data transmission rates of up to 2 megabits per second (Mbps). 3G technologies are occasionally referred to by the name broadband wireless.

Overview

The history of wireless cellular communications has had three distinct generations since its beginnings in the early 1980s. These generations are typically identified as follows:

- **1G (first generation of cellular communications):** This involved analog transmission of voice only (did not support data) over circuit-switched networks. 1G is represented by legacy systems such as the Advanced Mobile Phone Service (AMPS) introduced by AT&T in the early 1980s and still in use in some parts of North and South America. Other 1G systems included the Extended Total Access Communications System (E-TACS) used in Europe and Asia, the Nordic Mobile Telephone system used in Scandinavia, and the Total Access Communication System (TACS) used in Great Britain, Hong Kong, and Japan. 1G systems transmitted their traffic in clear (unencrypted) form.
- **2G (second generation):** This saw the development of digital cellular systems for transmitting digitally encoded voice and data (though data transmission speeds are limited to about 19.2 kilobits per second [Kbps]). Examples of 2G systems include Digital AMPS (D-AMPS), Time Division Multiple Access (TDMA), Code Division Multiple Access (CDMA), Global System for Mobile Communications (GSM), and Personal Communication Services (PCS) systems. 2G systems are circuit switched and support a variety of extended features such as encryption, Short Message Service (SMS), and fax transmission.
- **3G (third generation):** This was first envisioned by the International Telecommunication Union (ITU) in 1992 and had two aims. The first was to be a truly global digital packet-switched cellular system (as opposed to the circuit-switched 2G systems) for voice and data communications, where users could roam between continents without requiring new phones. The second was to provide consistent high-speed data transmission rates of up to 2 Mbps. Unfortunately, neither of these goals has been completely achieved.

In 1992 the ITU proposed a system called IMT-2000 as the single global 3G-based standard for cellular communications. In 1999 conflicts between carriers, regulators, and vendors in different countries and regions led to a compromise version of the IMT-2000 standard. The agreed-upon standard incorporated a mix of three different proposed versions, two of which use CDMA technologies and the third using TDMA. Existing CDMA providers will find it easier to upgrade to 3G technologies than TDMA providers will.

Types

Qualcomm has proposed a 3G upgrade for its popular 2G system cdmaOne, used throughout much of Asia and North America. The upgrade is called cdma2000 3XMC. It has recently been ratified by the ITU and is expected to provide real data rates of 1.117 Mbps. Other CDMA providers have proposed that an initial upgrade called cdma2000 1XMC be deployed first as an interim “2.5G” cellular system before full deployment of cdma2000 3XMC is achieved. The cdma2000 1XMC technology only supports real data rates of 144 Kbps, although vendor-proprietary extensions have been proposed to extend this.

Another 3G CDMA system similar to cdma2000 3XMC and currently being rolled out in some countries and regions is called Universal Mobile Telecommunications System (UMTS) or Wideband CDMA (W-CDMA) (carriers in Europe prefer the UMTS designation, but those in North America prefer W-CDMA or WCDMA). UMTS is designed to interoperate with existing GSM networks and will provide a natural upgrade path for these networks from 2G to 3G. The first country widely rolling out W-CDMA is Japan, which is using it to replace its Personal Digital Cellular (PDC) system, whose capacity is saturated. Unfortunately, UMTS/W-CDMA cannot be provisioned in the United States because the frequencies this technology requires have already been allocated by the Federal Communications Commission (FCC) for other uses. UMTS/W-CDMA supports wireless data transmission at 2 Mbps. Note, however, that this speed will be achievable for stationary users only—for mobile

environments this slows to 384 Kbps and for fast-moving vehicles such as a car on the highway, it is down to 144 Kbps.

Another proposed 3G system based on TDMA instead of CDMA is called EDGE (Enhanced Data Rates for Global Evolution). EDGE is an upgrade to existing General Packet Radio Services (GPRS) systems and supports data rates of 384 Kbps.

Prospects

3G was originally envisioned to become widespread by 2000 (hence the name of the original proposed IMT-2000 system), but these systems are only beginning to be deployed (now pushed back to between 2003 and 2005, depending on the country or region). They provide data rates less than those anticipated, and have developed interoperability problems that may not be easily resolved.

3G technology is also expensive to develop and deploy. In this regard, Europe has a head start on the United States; however, the total cost of deploying 3G throughout the European Union (EU) has been estimated to be as high as \$1 trillion. The long-term viability of many European 3G carriers may be affected by the high licensing fees imposed by governments for use of suitable radio spectrum. Most industry watchers expect a shakeout in the next few years, leaving only giants such as Deutsche Telekom, France Telecom, Vodafone, and a few others.

Many countries and regions, including the United Kingdom, Belgium, Germany, and Sweden, hold auctions to parcel off portions of 3G spectrum to the highest bidders. Carriers must quickly recoup these up-front costs to remain viable. Some countries and regions, such as Norway, Finland, France, and Spain, allocate spectrum on a fixed-fee basis to first-comers, but this practice is being challenged in the EU courts as a type of subsidy that is unfair and anticompetitive.

In the United States, AT&T laid out a road map in December 2000 for its deployment of 3G wireless that involves several intermediate steps. First, its existing TDMA network, which carries data at only 19.2 Kbps,

will be upgraded to GSM with an overlay of GPRS to support data transmission at 144 Kbps. Then GSM/GPRS will be upgraded to EDGE to support data transmission rates of 384 Kbps. Finally, W-CDMA will be deployed to support data at 2 Mbps. Meanwhile, CDMA carriers such as Sprint Corporation and Verizon Communications are upgrading their systems to cdma2000 and beyond. This split between W-CDMA, supported by AT&T, and cdma2000, supported by Verizon and Sprint, presents some interoperability problems for users in North America, but efforts are underway to resolve these issues.

Ultimately, when 3G systems are fully operational, they will provide mobile users with the equivalent of broadband Internet access, opening up a new world of wireless Web-based services and applications.

Notes

Although 3G wireless systems such as UMTS will be capable of supporting data transmission speeds of 2 Mbps, this will be for stationary clients only, which includes laptop computers equipped such as 3G PC cards. Transmission speeds for mobile clients such as 3G cell phones and handsets will likely top out at 384 Kbps or lower, depending on the environment's reception characteristics.

Because of the high costs and technical challenges associated with rolling out 3G systems, some cellular communications providers are rolling out unofficial "2.5G" systems as a kind of intermediate step along the way to the high-speed data rates of 3G. For more information, see the article "2.5 G" elsewhere in this chapter.

3.1 kHz bearer service

A service provided by some telcos for transmitting data over voice trunk lines.

Overview

When supporting 3.1 kHz bearer service communications, telco switches must have trunk-line echo cancellation turned off because echo cancellation will corrupt data transmissions sent over voice lines. This service is a legacy telecommunications technology that is no longer widely implemented.

Notes

Some carriers call this service data-over-voice (DOV).

4G

An envisioned fourth-generation wireless cellular system to supersede 3G (third-generation) cellular.

Overview

4G is a term sometimes applied to proposed wireless networking systems using Orthogonal Frequency Division Multiplexing (OFDM). OFDM is a modulation scheme theoretically capable of transmitting data at rates of 622 megabits per second (Mbps), which is much higher than the 2 Mbps of the 3G wireless systems that are only now beginning to be deployed. OFDM is currently defined in two implementations, one supported by the Institute of Electrical and Electronics Engineers (IEEE) and the other by the European Telecommunications Standards Institute–Broadband Radio Access Networks (ETSI-BRAN). These two implementations are different in some respects, and efforts are underway by the OFDM Forum to harmonize these systems to reduce the incompatibilities that could result once 4G systems begin to materialize. Apart from these difficulties, 4G wireless networking systems are more of a dream than a reality.

5-4-3 rule

A specification describing limitations on constructing certain kinds of Ethernet networks. The 5-4-3 rule applies specifically to Ethernet networks based on either the thinnet or thicknet cabling option.

5-4-3 rule. This rule restricts bus-style Ethernet networks to five total segments, four repeaters, and three populated segments.

Overview

According to the Ethernet specifications, thinnet (or thicknet) Ethernet network segments can be joined using repeaters to form larger networks, but there are limitations on how you can do this. The maximum number of segments you can join is five. To join these segments, you need to use four repeaters because Ethernet typically uses a bus topology in which all segments are joined linearly. However, in this configuration, no more than three of the segments can actually have computers attached to them, leaving two segments that are used only for extending distances rather than hosting computers. These two unpopulated segments are called inter-repeater links. You should not violate this rule when implementing Ethernet networks; otherwise, unreliable network communications might result.

6bone

A testbed for development of the next generation of the Internet Protocol (IP) protocol, IPv6.

Overview

The 6bone grew out of the IP Next Generation (IPng) project of the Internet Engineering Task Force (IETF) that led to the development of IPv6. It is an informal collaborative project among a number of groups around the world, operating under the oversight of the IETF's Next Generation Transition (NGtrans) Working Group. The 6bone began operation as a virtual network in which IPv6 packets were encapsulated in and tunneled over IPv4, but migration to native IPv6 is underway and should soon be completed.

The 6bone has been playing an important role in testing IPv6 before widespread migration from the current IPv4 (standard IP) networking protocol is recommended for public use. Projects such as Freenet6, developed by Viagénie, and vendors such as Nortel Networks and 3Com Corporation have provided IPv6 researchers with gateways for tunneling from their IPv6 testbed deployments through the IPv4 Internet and over the 6bone to test and become familiar with the new IPv6 protocol.

For More Information

The official site for the 6bone can be found at www.6bone.net. You can also find information there about how to join your network to the 6bone.

If you want to connect an individual workstation to the 6bone, you can use Freenet6, which can be found at www.freenet6.net. This site enables IPv6 end stations to connect to the 6bone through IPv4 tunneling over the Internet. You must have a dual IPv4/6 stack to connect. You can download a preliminary IPv6 stack from Microsoft Research at www.research.microsoft.com/msripv6.

6to4

A mechanism for connecting networks running IPv6 by tunneling through the IPv4 Internet.

Overview

6to4 was developed as a transitional scheme to support the operation of IPv6 within an IPv4 world until the backbone of the Internet is completely migrated to IPv6. 6to4 works by encapsulating IPv6 packets inside IPv4 packets and transmitting them over the existing IPv4 Internet. In this way, different islands of IPv6 connectivity can be linked across the IPv4 ocean that constitutes the Internet.

A special IPv6 prefix is used to identify an encapsulated 6to4 packet. This header is represented in IPv6 address notation as 2002::/16 and identifies the IPv6 address space specially reserved by IANA for 6to4 tunneling.

For More Information

In order to use 6to4, you must install a dual IPv4/6 protocol stack on your machine. Microsoft is integrating basic support for IPv6 into its Windows XP and Windows .NET Server operating system platforms. You can also download a pre-liminary IPv6 stack from Microsoft Research at www.research.microsoft.com/msripv6.

8mm

A format for tape backup developed by Exabyte Corporation.

Overview

8mm is the standard tape format for videotape, and Exabyte developed this format into a tape backup solution to take advantage of this medium's low cost. Typical 8mm tape drives can store up to 40 gigabytes (GB) of data on a tape, and data can be written to tape at speeds in excess of 6 megabytes per second (MBps) using compression or 3 MBps without compression. Exabyte 8mm tape drives are inexpensive, have high performance, and make an attractive tape backup solution for companies developing a disaster recovery plan.

10Base2

An Institute of Electrical and Electronic Engineers (IEEE) standard for implementing 10 megabits per second (Mbps) Ethernet over thin coaxial cabling.

Overview

10Base2 is based on the 802.3 specifications of Project 802 developed by the IEEE. It was ratified as an IEEE standard in 1985 and quickly found its way into corporate networks for small local area networks (LANs) connected to larger 10Base5 backbones.

10Base2 is sometimes referred to as thinnet or thin coax because it uses thin coaxial cabling for connecting stations to form a network (as compared to 10Base5, which uses a thicker form of cabling and hence is called thicknet). The designation 10Base2 is derived from the network's speed (10 Mbps), the signal transmission method (baseband transmission), and the maximum segment length (185 meters, rounded off to 200 with the zeros removed). Another popular nickname for this technology was Cheapernet because thinnet cabling was considerably less costly than thicknet cabling.

10Base2. A typical 10Base2 network.

Implementation

10Base2 networks are wired together using a bus topology, in which individual stations (computers) are connected directly to one long cable. The maximum length of any particular segment of a 10Base2 network is 607 feet (185 meters). If distances longer than this are required, two or more segments must be connected using repeaters. Altogether, a total of five segments can

be connected using four repeaters, as long as only three of the segments have stations (devices) attached to them. This is referred to as the 5-4-3 rule.

A 10Base2 segment should have no more than 30 stations wired to it. The minimum distance between these stations is 1.6 feet (0.5 meters). Stations are attached to the cable using BNC (British Naval Connector or Bayonet-Neill-Concelman) connectors, and the ends of the cabling have BNC cable connectors soldered or crimped to them.

10Base2 supports a maximum theoretical bandwidth of 10 Mbps, but in actuality the presence of collisions reduces this to more like 4 to 6 Mbps.

Notes

10Base2 networks are not deployed much anymore for two reasons. First, because their speed is limited to 10 Mbps, the networks perform poorly in today's bandwidth-hungry, Internet-connected world. Second, 10Base2 networks have a single point of failure—the long, linear bus cable used to connect the stations. A single break or loose connection brings down the entire network, thus every cable segment and station connection must be checked to determine the problem. If you are wiring an office for a small LAN with low bandwidth requirements, use 10BaseT instead, which is easier to manage and troubleshoot. For moderate to high bandwidth requirements, try using Fast Ethernet instead.

The two ends of a 10Base2 bus must be properly terminated. If they are not, signals will bounce and network communication will come to a halt.

10Base5

An Institute of Electrical and Electronic Engineers (IEEE) standard for implementing 10 megabits per second (Mbps) Ethernet over coaxial cabling.

Overview

10Base5 is based on the 802.3 specifications of Project 802 developed by the IEEE. It was developed as a standard in the early 1980s and became hugely popular in

corporate and campus networks. An earlier form of 10Mbps Ethernet developed by the DIX Consortium was superseded by 10Base5 when the IEEE 802.3 standard was created in 1983.

10Base5 is sometimes referred to as thicknet because it uses thick coaxial cabling for connecting stations to form a network (compared to 10Base2, which uses a thinner form of cable and is hence called thinnet). Another name for 10Base5 is Standard Ethernet because it was the first type of Ethernet to be implemented (it is also sometimes referred to as Original Ethernet, for obvious reasons). The designation 10Base5 is derived from the network's speed (10 Mbps), the signal transmission method (baseband transmission), and the maximum segment length (500 meters).

Implementation

10Base5 networks are wired together in a bus topology—that is, in a linear fashion using one long cable. The maximum length of any particular segment of a 10Base5 network is 1640 feet (500 meters). If distances longer than this are required, two or more segments must be connected using repeaters. Altogether, there can be a total of five segments connected using four repeaters, as long as only three of the segments have stations (computers) attached to them. This is referred to as the 5-4-3 rule.

A 10Base5 segment should have no more than 100 stations wired to it. These stations are not connected directly to the cable as in 10Base2 networks. Instead, a transceiver is attached to the cable, usually using a cable-piercing connector called a vampire tap. From the transceiver, a drop cable is attached, which then connects to the network interface card (NIC) in the computer. The minimum distance between transceivers attached to the cable is 8 feet (2.5 meters), and the maximum length for a drop cable is 164 feet (50 meters). Thicknet cable ends can have N-series connectors soldered or crimped on them for connecting segments together.

10Base5 was often used for backbones for large networks. In a typical configuration, transceivers on the thicknet backbone would attach to repeaters, which would join smaller thinnet segments to the thicknet

backbone. In this way a combination of 10Base5 and 10Base2 standards could support sufficient numbers of stations for the needs of a moderately large company.

10Base5 supports a maximum bandwidth of 10 Mbps, but in actual networks, the presence of collisions reduces this to more like 4 to 6 Mbps.

Notes

10Base5 networks are legacy networks that are no longer being deployed, although some companies might choose to maintain existing ones for cost reasons. The complexity and bandwidth limitations of 10Base5 networks render them largely obsolete. If you are wiring an office for a small local area network (LAN) with low bandwidth requirements, use 10BaseT instead. For moderate to high bandwidth requirements, try using Fast Ethernet. If you are implementing a backbone for today's high-speed enterprise networks, Gigabit Ethernet (GbE) is now the preferred technology.

The two ends of a 10Base5 bus must be properly terminated. If they are not, signals will bounce and network communication will come to a halt.

10BaseF

An Institute of Electrical and Electronic Engineers (IEEE) standard for implementing 10 megabits per second (Mbps) Ethernet over fiber-optic cabling.

Overview

10BaseF is based on the 802.3 specifications of Project 802 developed by the IEEE and differs from other forms of 10-Mbps Ethernet by using fiber-optic cabling instead of copper unshielded twisted-pair (UTP) cabling. The designation 10BaseF is derived from the network's speed (10 Mbps), the signal transmission method (baseband transmission), and the physical media used (fiber-optic cabling).

The 10BaseF standard actually consists of three separate standards describing different media specifications:

- **10BaseFB:** Defines how the synchronous data transmission occurs over the fiber-optic cabling.

Using 10BaseFB segments, you can cascade or link synchronous fiber-optic hubs in configurations that are longer than traditional 10BaseT Ethernet networks and contain up to 1024 stations. This standard is more expensive and is not as widely implemented as 10BaseFL.

- **10BaseFL:** Defines the characteristics of the fiber-optic link between the nodes and the hub or concentrator. 10BaseFL replaces the older standard for fiber-optic link segments, Fiber-Optic Inter-Repeater Link (FOIRL) segments, which was developed in the 1980s. 10BaseFL is the most commonly implemented version of 10BaseF.
- **10BaseFP:** Defines the implementation of a star topology that does not use repeaters. 10BaseFP stands for Fiber Passive, and its segments can be only 500 meters (1640 feet) in length with a maximum of 33 stations connected. This standard is rarely used today.

Implementation

10BaseF is similar to 10BaseT in that each station is wired into a hub in a star topology to form the network. The maximum length of any segment of 10BaseF fiber-optic cabling is 6600 feet (2000 meters), compared to the 328 feet (100 meters) supported by 10BaseT, making 10BaseF suitable for long-haul interconnects.

The recommended cabling type for 10BaseF networks is 62.5-micron diameter fiber-optic cabling. This cable can be terminated with either ST connectors or SMA connectors, depending on the vendor and the hub configuration. Two-strand multimode fiber-optic cabling is used, with one strand allotted for transmitting data and the other for receiving data.

Marketplace

Nowadays, 10BaseF is only supported in legacy 10 Mbps Ethernet equipment and has been superseded by 100 Mbps Fast Ethernet in most circumstances for network backbones and interconnects.

Notes

10BaseF is preferable to 10BaseT in environments that are electrically noisy, such as in industrial areas, near elevator shafts, or around other motors or generators.

Fiber-optic cabling is often used for running cables between buildings. Differences in ground potential between the ends of copper cabling can induce voltages that can damage networking equipment if the ends are not grounded properly. Fiber-optic cabling also supports faster speeds than copper UTP cabling and provides a more suitable upgrade option to Fast Ethernet and beyond.

The maximum signal loss or attenuation on a given segment should be no more than 12.5 decibels. Using too many connectors in a segment of fiber-optic cabling can cause the attenuation to exceed this figure, which can lead to signal loss.

10BaseT

An Institute of Electrical and Electronic Engineers (IEEE) standard for implementing 10 megabits per second (Mbps) Ethernet over twisted-pair cabling.

Overview

10BaseT is based on the 802.3 specifications of Project 802 developed by the IEEE and is the most popular form of 10-Mbps Ethernet. 10BaseT is deployed over structured cabling systems consisting of unshielded twisted-pair (UTP) cabling used for connecting end stations to centralized hubs to form a network. (Shielded twisted-pair [STP] cabling can also be used, but it never is.) The designation 10BaseT comes from the network's speed (10 Mbps), the signal transmission method (base-band transmission), and the physical medium used for transmission (twisted-pair cabling).

10BaseT became widely popular because of the earlier success of the Public Switched Telephone Network (PSTN), a hierarchical structured-wiring system to which 10BaseT bears many similarities. An advantage of 10BaseT over earlier 10 Mbps Ethernet systems such as 10Base5 and 10Base2 is that it is easier to manage because of the centralization of network traffic in hubs.

Implementation

In 10BaseT networks, end stations such as workstations and servers are wired together in a star topology to a central hub. The UTP cabling used for wiring should be Category 3 (Cat3) cabling, Category 4 (Cat4) cabling, or Category 5 (Cat5) cabling, terminated with RJ-45 connectors. Patch panels can be used to organize wiring and provide termination points for cables running to wall plates in work areas. Patch cables then connect each port on the patch panel to the hub. Usually most of the wiring is hidden in a wiring cabinet and arranged on a rack for easy access.

The maximum length of any particular segment of a 10BaseT network is 328 feet (100 meters). In practice this is not a limitation because a survey by AT&T indicated that about 99 percent of desktops in commercial buildings are located within 328 feet (100 meters) of a wiring closet. If distances longer than that are required, two or more segments may be connected using repeaters. The minimum length of any given segment is restricted to 8 feet (2.5 meters).

By using stackable hubs or by cascading regular hubs into a cascaded star topology, you can network large numbers of computers using 10BaseT cable. Although 10BaseT can support up to 1024 nodes, networks with no more than 200 or 300 nodes will yield the best performance by keeping collision domains small. Hubs can be hierarchically arranged to a depth of up to three levels in order to accommodate much larger networks, but performance declines significantly as the number of stations exceeds several hundred.

Notes

Although 10BaseT theoretically supports a maximum bandwidth of 10 Mbps, in actual networks the presence of collisions reduces throughput to about 4 to 6 Mbps.

The maximum length of a 10BaseT cable segment is not a result of the specifications for round-trip communications on an Ethernet network but rather a limitation caused by the relatively low signal strength of 10BaseT systems. With enhanced Category 5 (Cat5e) cabling, you might be able to sustain network communications effectively with cable lengths up to about 490 feet (150 meters), although this is not normally recommended.

10BaseT. A typical 10BaseT network.

When wiring a new 10BaseT network, always use Cat5e cabling. This will make it unnecessary to rewire your network should you decide to upgrade later to Fast Ethernet and beyond.

10GbE

An abbreviation for 10G Ethernet.

See: 10G Ethernet

10G Ethernet

Also known as 10GbE, an emerging form of networking technology based on Ethernet and operating at a speed of 10 gigabits per second (Gbps). 10GbE, which

stands for 10 Gigabit Ethernet, is the successor to Gigabit Ethernet (GbE) and will be standardized under the Institute of Electrical and Electronic Engineers (IEEE) 802.3ae working group.

Overview

10GbE is a switched-based technology that has similarities to and differences from earlier versions of Ethernet. It abandons the Carrier-Sense Multiple-Access with Collision Detection (CSMA/CD) Media Access Control (MAC) method of earlier versions, using instead separate send and receive channels. In other words, 10GbE operates only in full-duplex communications mode, similar to GbE and Full-Duplex Fast Ethernet. This does not eliminate contention, however, because 10GbE is designed to interoperate with slower forms of Ethernet where collisions may occur.

10GbE uses the same 48- to 1518-byte frame format as standard 10 megabits per second (Mbps) Ethernet and 100 Mbps Fast Ethernet, abandoning the jumbo frames supported by GbE. And unlike earlier versions of Ethernet, 10GbE operates exclusively over fiber-optic cabling, although efforts are being made to develop a form of 10GbE over copper cabling that can be used over the short distances needed within wiring closets. The maximum range for 10GbE will be 328 to 984 feet (100 to 300 meters) over multimode fiber and 25 miles (40 kilometers) over single-mode fiber. Laser wavelengths of 1310 and 1550 nanometers are used for medium- and long-haul transmission respectively.

Types

The driving force behind the development of 10GbE is twofold:

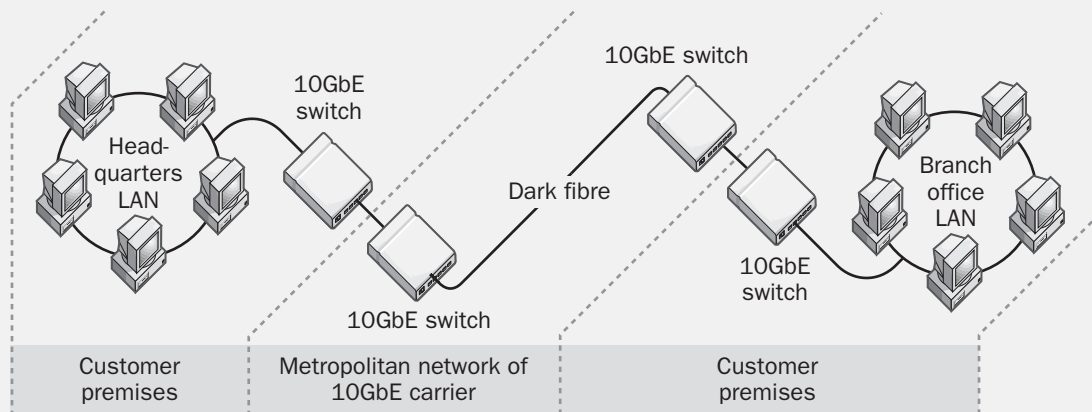

- Enterprise-level local area networks (LANs) that have deployed core switches with GbE interconnects (and even multiplexed GbE interconnects) are approaching saturation and require the higher backbone speed promised by 10GbE. Many server farms and clusters are being deployed today using 1000BaseT connections to network backbones. As a result, these backbones will soon face saturation unless a technology such as 10GbE can provide the necessary bandwidth to support these GbE farms (the Link Aggregation Control Protocol of 802.3ad

only supports up to 8 Gbps aggregated links between switches). The impending arrival of 64-bit PC architectures such as Intel's Itanium also promises to increase the rate at which servers will be able to process data, and new servers are appearing that are able to just saturate a 1 Gbps 1000BaseT NIC. The promise here is that 10GbE will enable network architects to build Ethernet wide area networks (WANs) as easily as they build Ethernet LANs today, without having to learn more complex technologies such as Asynchronous Transfer Mode (ATM) or Synchronous Optical Network (SONET).

- WAN service providers (carriers) see 10GbE as a simpler, less costly replacement for SONET/Synchronous Digital Hierarchy (SDH), and envisage a world of end-to-end Ethernet incorporating both LAN and WAN technologies. Although Ethernet gear only costs about a fifth of what SONET gear costs, incumbent carriers have invested heavily in SONET technologies and ATM, which may affect how quickly they adopt 10GbE. Startup carriers are therefore more likely to jump on the 10GbE bandwagon than existing carriers.

As a result of this twofold need of the carriers (for SONET-compatibility) and enterprise networks (for easy upgrading of core switches from GbE to 10GbE), two different versions of 10GbE are envisioned under the emerging IEEE 802.3ae standard. These versions, listed below, operate differently at the physical layer (PHY):

- **LAN version:** This is essentially just speeded-up GbE and will operate at exactly 10.0 Gbps and use standard Ethernet frames. The primary difference with GbE is that only full-duplex communications will be supported. This version is designed to be an easy upgrade for backbone switches in enterprise LANs.
- **WAN version:** This provides a method of transporting Ethernet frames over SONET/SDH at a speed of 9.58464 Gbps (identical to the current OC-192). This version is designed to maximize compatibility with carrier's existing SONET deployments in their long-haul lines.

① Aggregation of GbE backbone switches in enterprise LAN**② High-speed WAN access to remote sites**

10G Ethernet. Some scenarios where 10GbE could be deployed.

Implementation

Some envisioned uses for 10GbE include

- High-speed interconnects between GbE backbone switches in enterprise LANs
- Aggregation of multiple short-haul GbE links and high-speed campus-wide interconnects
- Switched connections to server farms and high-performance clusters

Some telecom carriers plan to replace their SONET/ATM rings with 10GbE in their Metropolitan Area Networks (MANs) to provide high-speed connections in the local loop between Central Offices (COs) and customer premises. These carriers will then be able to provision corporate users with 10GbE Ethernet WAN links to provide end-to-end Ethernet services across the WAN. Because this eliminates the need for costly packet-conversion equipment such as frame relay assembler/disassemblers (FRADs) or ATM access routers at the customer premises, 10GbE WAN services are likely to be much less costly than current T1 and frame relay services. Furthermore, 10GbE has almost no protocol overhead compared to ATM/SONET, which can have as much as 56 percent protocol overhead when implementing Automatic Protection Switching (APS) routines. The desire of carriers to implement 10GbE to save cost is a major force driving vendors to quickly develop 10GbE switching technologies. Due to its distance limitations, however, 10GbE is not expected to replace SONET/SDH for long-haul telecommunications links between cities or continents.

Issues

Most servers are not yet capable of utilizing the full potential of 10GbE because of limitations in processing power and bus speed, though advances in bus, memory, and storage technologies are closing the gap. With standard 1500-byte Ethernet frames being employed, servers would need to be able to process 833,000 frames per second, which is beyond their current limitations. One solution would be to employ Jumbo Frames similar to those used in GbE, but the 802.3ae standard does not cover this feature. The result is that some vendors are starting to implement their own proprietary Jumbo

Frame technologies, which raises concerns for future prospects of interoperability between 10GbE equipment from different vendors.

Prospects

Many users are looking forward to the day when carriers can provision their corporate networks with 10GbE. Carriers will likely supply these services using a bandwidth-on-demand model, allowing customers to replace their costly T1 and T3 lines with blocks of purchased bandwidth that can scale in real time to accommodate bursts of traffic. Application Service Providers (ASPs) are also waiting to take advantage of 10GbE to offer outsourced email and workflow applications that will perform as well as LAN-based implementations.

The IEEE published a draft standard (802.3ae) for 10GbE in September 2000, and the final standard is expected to be ratified in 2002. Until then, 10GbE equipment provided by vendors may involve proprietary technologies, and network architects should consider interoperability issues before committing budgets to this emerging technology. Another cost issue to consider is that existing copper and multimode fiber infrastructures would have to be replaced with more costly single-mode fiber if anything more than backbone switch interconnects is considered in a proposed 10GbE deployment.

Some of the vendors developing 10GbE plug-in backplane modules for their carrier-class backbone switches include Nortel Networks, Extreme Networks, and Foundry Networks. Because there is already demand in the corporate WAN market, service providers such as Yipes (www.yipes.com) are rapidly rolling out infrastructure to provide 10GbE carrier services in a number of cities across the United States and compete with local telco carriers selling T-carrier and frame relay services.

Notes

10GbE will support Simple Network Management Protocol (SNMP) and (Remote Network Monitoring) RMON at the PHY layer. This will enable carriers to remotely manage provisioned 10GbE services and should be a boon to enterprise network managers as well.

24 x 7

A term implying the uninterrupted running of network services. A 24 x 7 network is a network whose services and resources are available 24 hours a day, seven days a week, with virtually no downtime. A similar term is 24 x 7 x 365, which implies virtually no downtime during the entire year.

Overview

In today's emerging e-business economy, availability of the network and its resources and applications can make the difference between business success and failure. A variety of technologies can be used to approach the goal of 24 x 7 availability. One of the most successful is clustering, a technology in which an application runs redundantly on multiple servers. When one of the nodes in a cluster fails, the other nodes take on the workload of the failed node so that there's no interruption in service while the failed node is being repaired or replaced. Windows 2000 and .NET Server Advanced Server editions offer clustering services for high-availability line-of-business applications.

Other technologies important to the 24 x 7 goal include fault-tolerant hardware technologies. Examples are hot-swappable components, such as power supplies and hard disks that can be removed and replaced without the system having to power down or reboot. Fault-tolerant storage technologies such as RAID 1 or RAID 5 guard against data loss from disk failure. Cellular phones and pagers also play a role in attaining the 24 x 7 goal, as they allow businesses to keep in touch with administrators and technical support staff around the clock.

Notes

If you are an MIS (Manager of Information Services) or CIO (Chief Information Officer) running an e-business

that requires 24 x 7 uptime, it is wise to make sure your network administrators and support staff are adequately compensated—they must work hard to maintain a 24 x 7 networking environment. Also, such people can be difficult to replace, so it is advisable to do what you can to minimize turnover.

64-bit architecture

Any computing hardware based on a processor capable of manipulating 64 bits of information at a time and directly accessing up to 2^{64} bytes (16 exabytes) of different physical memory addresses.

Overview

The PC revolution of the 1990s was based to a large degree upon the x86 processor platform, a series of 32-bit processors developed by Intel Corporation. Compared to their 16-bit predecessors, these new processors could manipulate twice as many bits simultaneously and access up to 4 gigabytes (GB) of directly addressable memory, which provided more than enough processing power and memory space for most PC-based applications.

As the PC platform began to push its way into the high-end server platform previously dominated by Reduced Instruction Set Computing (RISC) processors, the demand for greater power and memory addressability grew. This need has been felt most in the area of enterprise-level database applications, which are processor and memory intensive in their requirements. To address these needs, two leading processor vendors, Intel and AMD, began development of 64-bit processors in the late 1990s.

Comparison

AMD's x86-64 architecture can run today's 32-bit operating systems and applications, but only when running in Legacy mode. Unfortunately, this mode limits addressable memory to 4 GB and provides no processing gain over the present Pentium III platform. In order to run true 64-bit operating systems and applications, the x86-64 architecture must be running in Long mode, which does not support backward compatibility with existing 32-bit applications and operating systems.

In order for Intel's IA-64 architecture to run legacy 32-bit software, an x86 hardware emulation mode is provided. When 32-bit software is run using emulation mode, however, performance is generally slower than that of a typical Pentium III processor.

In order to properly run legacy software on Itanium (or on Sledgehammer running in Long mode) and enable such software to address the full 64-bit address space, the software needs to be recompiled to produce a binary bit-image appropriate to the selected 64-bit platform. Unfortunately, these binary images are different for the two architectures, so either a single architecture will win out or vendors will need to compile two different versions for the two platforms. Until existing software is recompiled, or until 64-bit operating systems and applications are developed from scratch, the usefulness of these two new architectures will be limited as far as the business enterprise is concerned.

Architecture

Intel's new 64-bit Itanium chip uses a radically new architecture called IA-64 that differs in fundamental ways from the x86 architecture used in all of its earlier 32-bit processors, from the 386 through the Pentium III Xeon. Itanium uses a Very Long Instruction Word (VLIW) algorithm that allows it to read strings containing multiple instructions. Using a technique called Explicitly Parallel Instruction Computing (EPIC), Itanium can then execute up to six instructions per clock cycle, which greatly enhances performance over 32-bit processors (not just Intel x86 processors, but also 32-bit RISC and complex instruction set computing [CISC] processors) and eliminates the need for complicated algorithms such as the Out-of-Order Processing implemented in Pentium chips.

Itanium processors are capable of performing 6 billion floating-point operations per second (6 gigaflops) and support up to 512-way symmetric multiprocessing (SMP) for the most transaction-intensive e-commerce and database applications. Itanium uses a new motherboard interface and requires a bus speed of 366 MHz.

AMD's new 64-bit Sledgehammer chip uses an architecture called x86-64 that is a natural evolution from the x86 standard, and AMD's 32-bit Athlon processor.

Sledgehammer operates in two modes: long mode, which runs native 64-bit operating systems and applications, and legacy mode, which supports existing 16-bit and 32-bit operating systems and applications. Sledgehammer uses a motherboard with a Plastic Pin Grid Array (PPGA) processor slot and requires a 266 MHz system bus.

Prospects

Both architectures have their camps supporting them. Intel's IA-64 architecture is supported by Microsoft Corporation, Hewlett-Packard, IBM, Compaq Computer Corporation, and others, and is likely to be the platform of choice for users of Microsoft Windows once Microsoft releases its 64-bit version of Windows currently under development. AMD's x86-64 architecture is supported by Sun Microsystems, which has plans to port Solaris (a version of UNIX) to x86-64, and by the Linux community, which is working on a similar port.

Notes

Some software vendors have developed ways of going beyond the hardware limitations of 32-bit processors that limit addressable physical memory to 4 GB. Examples include Microsoft Windows 2000 Advanced Server and Microsoft Windows 2000 Datacenter Server, both of which employ a technique called Physical Address Extension (PAE) to enable them to address 8 GB and 64 GB of memory respectively.

64-bit Windows

A version of Microsoft Windows 2000, Windows XP, and Windows .NET Server designed to operate on computers using Intel's new IA-64 (64-bit) processor architecture.

Overview

64-bit Windows is designed to support today's most processor- and memory-intensive business applications. These applications include e-commerce, data mining, online transaction-processing, high-end graphics, and

high-performance multimedia applications. Based on Intel's 64-bit processor architecture called IA-64, which is first realized in the Itanium chip, 64-bit Windows is fully compatible with the Win32 API, allowing developers to develop and compile code for both the 32-bit and 64-bit platforms with equal ease. The main advantage of using a 64-bit processor architecture is that the amount of directly addressable physical memory increases from 64 GB for 32-bit Windows 2000 and Windows .NET Server Datacenter Server to a staggering 16 terabytes (TB) for the new platform. (A terabyte equals 1024 gigabytes.) This means that large databases can be preloaded in-to memory to provide vastly improved data access times, improving the performance and efficiency of enterprise-level applications.

80/20 rule

A rule of thumb that says that 80 percent of network traffic is local and only 20 percent is destined for remote networks.

Overview

The 80/20 rule was developed in the era of traditional routed Ethernet networks and is now considered a classical description of local area network (LAN) traffic patterns that no longer applies. The main consideration here is the Internet, and corporate use of Internet access means that ever-increasing amounts of remote traffic are being routed through LANs. The 80/20 rule was used in the 1980s to help enterprise network architects plan and design large-scale routed networks.

Notes

Other types of 80/20 rules exist. For example, in programming, the 80/20 rule says that 80 percent of the benefit in coding an application comes from 20 percent of the work involved. In other words, prioritize your development tasks to achieve the most in the time available. The original 80/20 rule seems to have originated

with Vilfredo Pareto, an early 20th-century economist who stated that 80 percent of the volume of product produced comes from only 20 percent of the producers who make it. Another modern variant says that 80 percent of your business comes from only 20 percent of your customers, so identify these customers and give them premier service.

100BaseFX

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 100 megabits per second (Mbps) Ethernet over fiber-optic cabling.

Overview

100BaseFX is based on the 802.3u standard, which is an extension of the 802.3 standard of Project 802 developed by the IEEE. It's a type of Fast Ethernet that is often used for wiring campus backbones using fiber-optic cabling. The designation 100BaseFX is derived from the network's speed (100 Mbps), the signal transmission method (baseband transmission), and the physical medium used for transmission (fiber-optic cabling).

Implementation

100BaseFX networks are wired together in a star topology using fiber-optic cabling and 100-Mbps fiber-optic hubs or Ethernet switches. 100BaseFX systems may be interconnected with 100BaseTX, 100BaseT4, and 10BaseT systems using auto negotiating hubs and switches with suitable ports. Two-strand fiber-optic cabling is required, and ST, SC, and MIC connectors are all supported. Signaling is at 125 megahertz (MHz), which when combined with the 80 percent efficiency of the 4B5B line coding mechanism used results in an overall transmission speed of 100 Mbps.

The maximum length of any segment of fiber-optic cabling connecting a station (computer) to a hub in 100BaseFX is 1350 feet (412 meters), and not 1480 feet (450 meters) as some sources indicate. The grade of fiber-optic cabling used is usually two-strand multimode fiber-optic cabling, with one strand carrying transmitted data and the other strand receiving data. However, you can also use two-strand single-mode fiber-optic cabling. If multimode fiber-optic cabling is

used, the variety used is typically a grade with a 62.5-micron core diameter.

Repeaters can be used to extend the length of cabling and for interfacing between 100BaseFX/TX and 100BaseT4 segments. The maximum allowable distances with repeaters are 2 kilometers using multimode fiber-optic cabling and 10 kilometers using single-mode fiber-optic cabling. Only one or two repeaters can be used per collision domain, depending on whether Class I or Class II repeaters are used.

Notes

100BaseFX and a related standard, 100BaseTX, are sometimes collectively referred to as 100BaseX.

When using 100BaseFX with repeaters for backbone cabling runs, Ethernet switches cannot be more than 1350 feet (412 meters) apart when running in half-duplex mode and 6600 feet (2000 meters) apart when running in full-duplex mode.

100BaseT

Another name for Fast Ethernet and thus for all 100 megabits per second (Mbps) Ethernet varieties. Also sometimes used interchangeably with 100BaseT4.

See: Fast Ethernet

100BaseT4

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 100 megabits per second (Mbps) Ethernet over twisted-pair cabling.

Overview

100BaseT4 is based on 802.3u, which is an extension of the 802.3 specifications of Project 802 developed by the IEEE. 100BaseT4 is the most commonly used implementation of Fast Ethernet today. The designation 100BaseT4 is derived from the network's speed (100 Mbps), the signal transmission method (baseband transmission), and the physical medium used for transmission (all four pairs of wires in standard twisted-pair cabling). 100BaseT4 is now considered legacy technology and has been largely superseded by 100BaseTX.

100BaseT4. A typical 100BaseT4 network.

Implementation

100BaseT4 networks are wired together in a star topology using unshielded twisted-pair (UTP) cabling and 100-Mbps hubs or Ethernet switches. The UTP cabling involved may be Category 3 (Cat3), Category 4 (Cat4), or Category 5 (Cat5) cabling—with Cat5 cabling and enhanced Category 5 (Cat5e) cabling being the most commonly used solutions nowadays.

100BaseT4 uses all four pairs of wire in standard UTP cabling, for signaling with signaling rates of 25 megahertz (MHz) and an 8B6T line coding mechanism. One pair is used exclusively for transmission and a second pair for reception. The other two pairs are bidirectional and can be used either to transmit or to receive data as required. In this way, three of the four wire pairs are used at any given time to provide half-duplex transmission or reception of signals. Sharing three pairs of wires for data transfer allows 100BaseT4 to make use of lower-grade Cat3 cabling already installed in many older buildings.

The maximum length of any segment of cabling connecting a station (computer) to a hub is 328 feet (100 meters). This ensures that round-trip signaling specifications are

met, because violating these specifications can produce late collisions that disrupt network communications. The Electronic Industries Alliance/Telecommunications Industry Association (EIA/TIA)—recommended length of cabling between the station and the wiring closet is only 295 feet (90 meters), allowing up to 32 feet (10 meters) more of cabling for patch cables used to connect patch panels to hubs or switches. The pinning of the RJ-45 connectors used for 100BaseT4 wiring is the same as for 10BaseT wiring.

Notes

Make sure all your cabling, connectors, and patch panels are fully Cat5-compliant. For example, ensure that when UTP cabling is connected to patch panels, wall plates, or connectors, the wires are not untwisted more than half an inch at the termination point.

100BaseT4 hubs and switches are typically available in an autosensing 10/100-Mbps variety for interoperability with older 10BaseT networks and to facilitate an easy upgrade from 10BaseT to 100BaseT.

100BaseTX

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 100 megabits per second (Mbps) Ethernet over twisted-pair cabling.

Overview

100BaseTX is based on 802.3u, which is an extension of the 802.3 specifications of Project 802 developed by the IEEE. The designation 100BaseTX is derived from the network's speed (100 Mbps), the signal transmission method (baseband transmission), and the physical medium used for transmission (the same two pairs of wires in standard four-wire twisted-pair cabling that are used for 10BaseT Ethernet).

Implementation

100BaseTX networks are wired together in a star topology using either unshielded twisted-pair (UTP) cabling or data-grade shielded twisted-pair (STP) cabling. If UTP cabling is used (which is the most common scenario), it must be Category 5 (Cat5) cabling or enhanced Category 5 (Cat5e) cabling. Stations are

connected together using hubs or switches. Unlike 10BaseT hubs, which can be hierarchically connected up to three levels deep, 100BaseTX hubs can only be connected two layers deep, which imposes additional distance limitations and may necessitate rewiring of existing cabling before upgrading from 10BaseT to 100BaseTX.

100BaseTX. A typical 100BaseTX network.

100BaseTX uses the two pairs of wires in twisted-pair cabling that are used by 10BaseT networks, with one pair of wires used for transmission and the other used for reception. With the appropriate equipment, 100BaseTX is capable of supporting both the familiar half-duplex Ethernet used by 10BaseT and newer full-duplex Ethernet signaling technologies. 100BaseTX employs a signaling rate of 125 megahertz (MHz) for each pair of wires, which, because the 4B5B line coding algorithm used is only 80 percent efficient, translates into a data transmission speed of 100 Mbps.

The maximum length of any segment of cabling connecting a station to a hub is 328 feet (100 meters). This ensures that round-trip signaling specifications are met, because violating these specifications can produce late collisions that disrupt network communications. The

pinning of the RJ-45 connectors used for 100BaseTX wiring is the same as for 10BaseT wiring with wires 1 and 2 used for transmission and wires 3 and 6 used for reception. This enables 100BaseTX autosensing hubs and switches to operate in mixed 10/100 Mbps Ethernet networks.

Notes

The maximum distance between 100BaseTX hubs and bridges or switches is 738 feet (225 meters), further than the maximum hub-station distance of only 328 feet (100 meters).

100BaseTX and a related standard, 100BaseFX, are sometimes collectively referred to as 100BaseX.

Although the maximum length of segments joining stations to hubs is 328 feet (100 meters), the Electronic Industries Alliance/Telecommunications Industry Alliance (EIA/TIA) recommends only 295 feet (90 meters) of cabling between the station (computer) and the wiring closet, allowing up to 32 feet (10 meters) more of cabling for patch cables used to connect patch panels to hubs or switches.

Make sure all your cabling, connectors, and patch panels are fully Cat5-compliant. Make sure that when UTP cabling is connected to patch panels, wall plates, or connectors, the wires are not untwisted more than half an inch at the termination point.

100VG-AnyLAN

Also called 100BaseVG, a 100 megabits per second (Mbps) networking technology that at one time was a serious alternative to Fast Ethernet, but which now is considered legacy technology.

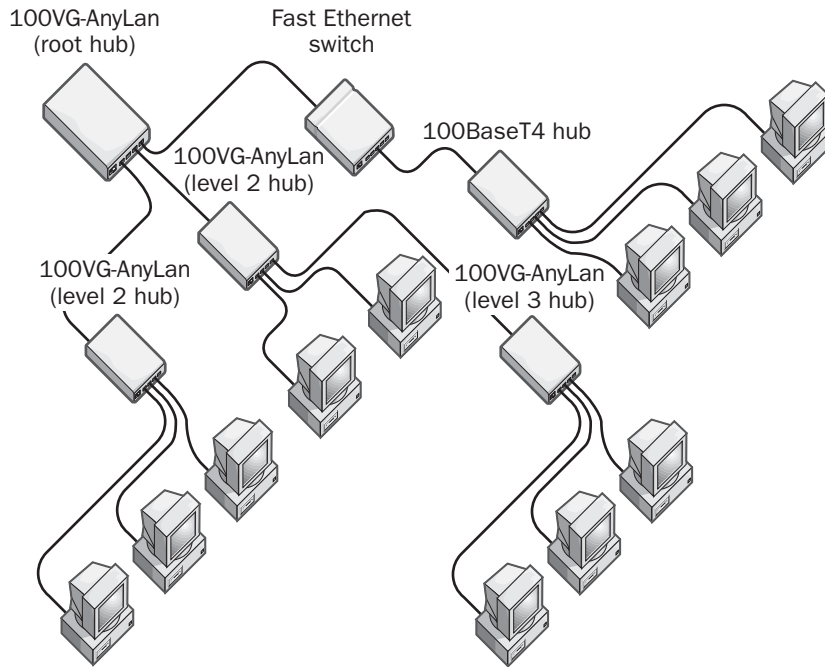

Overview

100VG-AnyLAN is defined by the 802.12 standard of the Institute of Electrical and Electronics Engineers (IEEE) Project 802. It is a local area network (LAN) communications technology developed by Hewlett-Packard and AT&T around 1994. 100VG-AnyLAN is similar to Fast Ethernet in its speed (100 Mbps) and ability to be deployed in both shared-media (hub-based) and switched implementations. It differs, however, in its media access method, because it uses demand priority instead of the Carrier-Sense Multiple-Access with Collision Detection (CSMA/CD) method used by Ethernet.

Implementation

100VG-AnyLAN networks are wired together in a star topology using unshielded twisted-pair (UTP) cabling, shielded twisted-pair (STP) cabling, or fiber-optic cabling. If UTP cabling is used, it can be Category 3 (Cat3), Category 4 (Cat4), or Category 5 (Cat5) cabling—with Cat5 cabling or enhanced Category 5 (Cat5e) cabling preferred. When using UTP Cat3 or Cat4 cabling, the maximum length of a segment is 100 meters (328 feet). With UTP Cat5 cabling or STP cabling, the maximum length of a segment is 656 feet (200 meters). When using multimode fiber-optic cabling, the maximum length is 6600 feet (2000 meters).

100VG-AnyLAN uses all four pairs of wires in UTP cabling with 25 megahertz (MHz) signaling for each pair. 100VG-AnyLAN uses a special coding scheme called quartet signaling, which makes it possible to transmit data over all four pairs of wires in a UTP cable simultaneously. This means that special 100VG-AnyLAN hubs are required to support demand priority media access. Otherwise, the frame format, topology, and other specifications of 100VG-AnyLAN are the same as for Ethernet.

100VG-AnyLAN. A typical 100VG-AnyLAN network.

100VG-AnyLAN employs the demand priority Media Access Control (MAC) method specified by the IEEE 802.12 standard. Demand priority means that the central hub controls which station is allowed to transmit data (only one station is allowed to transmit at any given moment). This eliminates the overhead of collisions and means that 100VG-AnyLAN networks have an efficiency of 100 percent compared to the 60-70 percent efficiency of contention-based Fast Ethernet networks. Demand priority works by having the hub poll each station successively in round-robin fashion until a station indicates it has data to transmit, whereupon control is passed temporarily to the transmitting station.

If multiple hubs are used, these are connected hierarchically with the top hub, called the root hub, being the master controller for the network. If a station is connected to a local hub other than the root hub in a large 100VG-AnyLAN network, the local hub detects the station's request to transmit data during regular polling and then forwards this request to the next highest hub in its hierarchy until it reaches the root hub, which communicates with the local hub, telling it when it is

allowed to service the station's request. Thus even in a large 100VG-AnyLAN network with a hierarchy of hubs, only one station is allowed to transmit data at any given time. 100VG-AnyLAN supports five levels of hubs in a hierarchy, but performance is best if cascading is limited to only three levels.

Because demand priority is a deterministic rather than contention-based media access method, stations cannot join the network on their own and begin transmitting data. Instead, when a station is first connected, it waits to be polled by the hub and then transmits a training sequence of special frames that enables the station to determine the frame type in use and other network restrictions. This training sequence temporarily suspends polling by the hub, but takes only 5 msec to be completed and so does not seriously disrupt network communications.

Advantages and Disadvantages

100 VG-AnyLAN offers greater efficiency due to elimination of collisions, but another advantage that it has over Fast Ethernet is that it supports both 802.3 Ethernet frames and 802.5 Token Ring frames, although a

single hub cannot support both at the same time (all hubs on any given 100VG-AnyLAN network must be configured to support the same frame type, either 802.3 or 802.5).

Yet another advantage 100VG-AnyLAN has over Ethernet is that it has built-in support for traffic prioritization. Two levels of traffic are recognized by 100VG-AnyLAN hubs: normal priority and high priority. High-priority traffic requests are serviced immediately by the local hub without the need for that hub to first communicate with the network's root hub. All network traffic is then suspended until the high-priority transmission is completed.

Marketplace

Although 100VG-AnyLAN is in some ways a superior technology to Fast Ethernet due to its greater efficiency and inherent support for traffic prioritization, it has not been widely deployed. This is mainly due to limited vendor support, which has kept prices high and made Fast Ethernet more affordable. Furthermore, Fast Ethernet is simpler and is completely compatible with widely deployed 10BaseT Ethernet networks and forms the natural upgrade path for these networks.

568-A

A wiring standard for twisted-pair cabling defined by the Telecommunications Industry Association (TIA).

Overview

The 568-A standard was originally intended for analog voice applications but is generally used in data networks as well. The main difference between 568-A and the competing 568-B standard is in the pin layouts for RJ45 jacks, which generally terminate unshielded twisted-pair (UTP) cabling. The pin layout for 568-A wiring is technically referred to as T568A. For a comparison of these two wiring schemes, see the next article, "568-B."

Notes

The T568A wiring scheme is preferred in Canada, although this has been changing recently.

568-B

A wiring standard for twisted-pair cabling defined by the Telecommunications Industry Association (TIA).

Overview

The 568-B standard was designed for data transmission over building wires used in computer network and telecommunications systems. It differs from the competing 568-A standard mainly in the pin layouts for the RJ45 jacks that are normally used to terminate unshielded twisted-pair (UTP) cabling. The pin layout for 568-B wiring is technically referred to as T568B, and that for 568-A cabling systems is called T568A. The drawing illustrates these differences between the two wiring systems.

Key		
Pair number	Color	Symbol
1	Blue	——
2	Orange	-----
3	Green	——
4	Brown	-----

568-B. Comparison of pin layouts in RJ45 connectors between 568-A and 568-B.

Notes

For 10BaseT and 100BaseT Ethernet networks, only two pairs of wires are used for data transmission, but 1000BaseT Gigabit Ethernet (GbE) uses all four pairs. As a result, running GbE over a cabling infrastructure that contains a mixture of 568-A and 568-B terminations will cause signaling problems that can be hard to troubleshoot.

802.1p

An Institute of Electrical and Electronics Engineers (IEEE) standard specifying a prioritization scheme for Ethernet networks that support the 802.1Q virtual local area network (VLAN) standard. The 802.1p standard allows a rudimentary form of quality of service/class of service (QoS/CoS) on Layer-2 switched networks.

Overview

One of Ethernet's biggest drawbacks is its lack of an inherent mechanism for prioritizing network traffic.

The new 802.1p standard tries to resolve this by making use of three reserved bits in the tags appended to packets by devices that support the 802.1Q VLAN standard. Employing these three bits enables $2^3=8$ different priority levels to be assigned to each packet of data, allowing switches and routers to handle these different types of traffic according to preconfigured schemes. The table shows the eight different traffic classes that correspond to priorities 0 (binary 000) through 7 (binary 111) according to IEEE recommendations.

Traffic Classes by Priority

Priority	Type of Traffic
0	Standard best-effort LAN traffic (default priority setting)
1	Lowest priority, used primarily for traffic that should not be allowed to affect other forms of traffic, for example, bulk file transfers
2	Unallocated at present
3	Excellent effort—in other words, best-effort delivery for important data
4	Controlled load—supports admission control for mission-critical business traffic
5	Low-priority multimedia traffic with jitter and latency less than 100 ms
6	High-priority multimedia traffic with jitter and latency less than 10 ms
7	Highest priority for traffic that controls the network infrastructure

Marketplace

An example of an Ethernet switch that supports the 802.1p standard is the ProCurve 8000M from Hewlett-Packard. These switches also support 802.1Q, 802.3ad, QoS, and port security.

Notes

Ethernet networks that use Layer 3 switches can implement more sophisticated CoS/QoS schemes such as Differentiated Services (DiffServ) and Integrated Services with resource Reservation Protocol (IntServ/RSVP). For mixed Layer 2/3 networks, the 802.1p standard provides standard mappings between these Layer-3 CoS/QoS mechanisms and the Layer-2 802.1p prioritization scheme.

802.1Q

An Institute of Electrical and Electronics Engineers (IEEE) standard defining the architecture and operation of virtual local area networks (VLANs).

Overview

The 802.1Q VLAN standard ratified in 1999 allows a tag of 4 bytes to be appended to packets by network hosts and Layer 2/3 switches in Ethernet networks. This tag identifies the VLAN to which the given packet belongs. For a more detailed explanation, see the article “virtual LAN (VLAN)” elsewhere in this book. The 4 bytes of tag information are embedded into the standard Ethernet header by dividing them between the 2-byte tag protocol identifier (TPID) field and the 2-byte tag control information (TCI) field. The TCI field consists of

- **User priority field:** This three-bit field forms the basis of 802.1p traffic prioritization schemes in Level-2 switched networks.
- **Canonical format indicator:** This is a one-bit field that is used to toggle VLAN formats.
- **VLAN Identifier (VID):** This is a 12-bit field that identifies the VLAN to which the packet belongs. Up to 212 (4096) VLANs can be defined.

Marketplace

Many vendors produce Ethernet switches compatible with the 802.1Q standard, although mostly at the high end of their switching gear offerings. At the workgroup level, fewer vendors support this standard in their switches. For example, the low-end Catalyst 2900 switches from Cisco Systems do not support 802.1Q, but Hewlett-Packard's new ProCurve 10/100 stackable switches with Gigabit Ethernet (GbE) backbone transceivers do.

802.2

The Institute of Electrical and Electronics Engineers (IEEE) standards for the Logical Link Control (LLC), defining its operation for all network architectures that follow the Open Systems Interconnection (OSI) model. The physical layer (PHY) and media access control (MAC) layer specifications are specified for a particular

technology under the 802 committee that deals with them (for example, 802.3 deals with Ethernet and 802.5 with Token Ring). The IEEE 802.2 working group is no longer active.

802.3

The Institute of Electrical and Electronics Engineers (IEEE) working group concerned with Ethernet in its many forms. Although this set of standards is generically referred to as Ethernet, this term is actually a trademarked version of 802.3.

Overview

The 802.3 standards cover those relating to local area networks (LANs) based on Carrier-Sense Multiple-Access with Collision Detection (CSMA/CD) as their Media Access Control (MAC) method, in other words with

- 10 Mbps Ethernet (original 802.3 standard)
- 100 Mbps Fast Ethernet (802.3u)
- 1 Gigabit Ethernet (GbE) (802.3z and 802.3ab)
- 10 Gigabit Ethernet (under development)

Some recently ratified standards of the 802.3 working group include

- **802.3z:** Gigabit Ethernet (1998)
- **802.3ab:** 1000Base-T (GbE over copper) (1999)
- **802.3ac:** Tag switching in virtual local area networks (VLANs) (1998)
- **802.3ad:** Link aggregation (2000)

Some of the projects the 802.3 working group is currently involved with include

- **802.3ae:** 10 Gigabit Ethernet (10GbE)
- **802.3af:** Transmission of electrical power over unshielded twisted pair (UTP) cabling to power Ethernet devices

Notes

802.3 is also used to refer to the frame format used in Ethernet frames. See the article “frame type” elsewhere in this book for more information.

802.3ad

An Institute of Electrical and Electronics Engineers (IEEE) standard for link aggregation of Ethernet switch ports and network interface cards (NICs) to combine multiple data streams into a single large stream.

Overview

Prior to 802.3ad, many vendors of Fast Ethernet and Gigabit Ethernet (GbE) gear developed their own proprietary trunking protocols for aggregating multiple links together into a single higher speed link. Examples include Adaptec’s Duralink technology and Cisco Systems’ Inter-Switch Link Trunking (ISL) protocol. The 802.3ad standard was developed to promote interoperability between switches from different vendors. The need for such technology is increasingly apparent in a world of streaming media and outsourcing Line of Business (LOB) functions to Application Service Providers (ASPs).

The 802.3ad standard covers all versions of Ethernet (10, 100, and 1000 megabits per second [Mbps]) and enables multiple links of the same or different speeds to be aggregated into a single logical link. For example, two 1-gigabit-per-second (Gbps) GbE ports can be combined to make a single 2-Gbps link, or a 1-Gbps GbE port and a 100-Mbps Fast Ethernet port can be combined to create a single 1100-Mbps link. The maximum bandwidth supported by aggregated 802.3ad links is 8 Gbps—in other words, up to eight full duplex 1-Gbps GbE ports can be combined into a single fat

data pipe. The protocol used to accomplish this is called the Link Aggregation Control Protocol (LACP).

Advantages and Disadvantages

The main advantage of 802.3ad is that additional bandwidth for network backbones and connections to server farms can be added incrementally as needed, thus providing greater scalability at minimum cost. The 802.3ad standard includes a mechanism for load balancing traffic across aggregated links. It also supports fault tolerance to handle the failure of any link within an aggregated set of links by automatically rerouting traffic through a different link. This fault-tolerant failover feature makes 802.3ad ideal for mission-critical point-to-point links.

Marketplace

The 802.3ad standard was ratified in July 1999, and 802.3ad-compliant products are just beginning to appear, primarily GbE backbone switches and GbE NICs for high-end server clusters.

802.3af

An emerging Institute of Electrical and Electronics Engineers (IEEE) standard that allows data-carrying unshielded twisted pair (UTP) cabling to carry not only data but also electricity for powering Ethernet networking devices.

Overview

Traditionally, in networking devices the wires carrying power to run the device and the wires carrying data to and from the device are kept separate. This is done to isolate the sensitive data-handling electronics from the high power levels required by the device. Many newer network-capable devices such as hubs, Internet Protocol (IP) telephones, and Personal Digital Assistants (PDAs) require only a few watts to operate, and 802.3af

promises to simplify the operation of these devices. Instead of separate cables for carrying data and power, 802.3af devices will require only data connections and will receive their power over these connections. The advantage is that fewer cables need to be deployed and used for compliant networking devices, which promises to make Voice over IP (VoIP) telephone equipment as easy to deploy and use as traditional Plain Old Telephone Service (POTS) telephones, which communicate through and are powered by the same RJ-11 outlet found in private homes.

802.3af allows up to 10 watts of power to be carried over Category 3 (Cat3) or Category 5 (Cat5) cabling when running 10BaseT or 100BaseTX Ethernet on the network. The standard provides for the transmission of both AC and DC power as required. To protect non-802.3af devices from damaging power levels that could fry their electronics, the 802.3af standard includes a handshaking protocol to enable 802.3af-compliant devices to be recognized before transmitting power to them.

Marketplace

PowerDsine, Siemens, and Lucent Technologies are vendors that have developed early versions of 802.3af-compliant switches, hubs, and IP telephony equipment. Refer to these vendors' Web sites for the latest information on these products.

Notes

Cisco Systems already has its own proprietary scheme called Inline Power for power transmission over data lines. The Cisco version supports DC power transmission over UTP cabling.

802.9

The Institute of Electrical and Electronics Engineers (IEEE) standards for isochronous local area networks (LANs) for simultaneous transmission of data and voice/video. The only developed form of this standard is the 802.9a isoEthernet specification.

Overview

Isochronous means “at a precise time,” which indicates that 802.9 technologies operate using clocked signals in order to deliver data according to a rigid time schedule. In this fashion 802.9 resembles the Public Switched Telephone Network (PSTN), a circuit-switched network operating at 8 kilohertz (kHz) clocking rate and transmitting one byte every 125 microseconds to produce an overall channel (called a B channel) whose bandwidth is 64 kilobits per second (Kbps).

The isoEthernet standard developed in conjunction with National Semiconductor combines traditional 10BaseT Ethernet data transmission at 10 megabits per second (Mbps) with a separate 6.144 Mbps isochronous data channel for transporting time-sensitive traffic such as voice and video. The isochronous data channel (called the Circuit channel) consists of 96 B-channels of 64 Kbps each. IsoEthernet’s total bandwidth, therefore, is 16 Mbps, but this is split between the two types of transmission: data and voice/video. There are also some additional channels (D-, M-, and P-channels) that are used for control and maintenance, but these use only about 200 Kbps of bandwidth. The 10 Mbps of

10BaseT data and 6.144 Mbps of isochronous transmission are carried on the same unshielded twisted pair (UTP) cabling system by incorporating time-division multiplexing (TDM) techniques.

Notes

The IEEE 802.9 working group is no longer active and isoEthernet is now considered a legacy technology.

802.11

A set of Institute of Electrical and Electronics Engineers (IEEE) standards for wireless networking designed to do for wireless networking what the 802.3 standards have done for Ethernet: provide clear guidelines for vendors to develop technologies that are standards-based, interoperable, and can operate at different speeds and frequencies and also can use different encoding mechanisms.

Overview

Three standards are currently ratified under 802.11:

- **802.11:** The original wireless networking standard supporting data rates of up to 2 megabits per second (Mbps) and now superseded by 802.11b. This standard was approved in June 1997 and provided for both direct sequence spread spectrum (DSSS) and frequency hopping spread spectrum (FHSS) physical-layer (PHY) transmission methods. 802.11 also supported transmission over infrared, but no products were developed for this method. 802.11 allows data to be transmitted at either 1 Mbps or 2 Mbps, depending on which is the highest rate negotiable in a given configuration of client and access point (the further the distance between them, the lower the possible data rate).

- **802.11b:** A standard for wireless networking supporting data rates of up to 11 Mbps and operating in the unlicensed 2.4 GHz Industrial, Scientific, and Medical (ISM) band. 802.11b transmission is standardized on DSSS.
- **802.11a:** A standard supporting higher data rates of up to 54 Mbps and operating in the 5 GHz UNII (Unlicensed National Information Infrastructure) band. 802.11a transmission is similarly standardized on DSSS.

Of these standards, 802.11b is currently the most widely deployed, with support from over 20 vendors, and 802.11 is considered legacy and is being phased out. Part of the success of 802.11b is due to the successful lobbying of the Wireless Ethernet Compatibility Alliance (WECA), which has helped ensure adherence to standards and interoperability between equipment from different vendors. The 802.11a standard is newer and is seen as the next generation for wireless networking and the natural upgrade path for companies needing its higher data transmission rates.

All these standards use the same Media Access Control (MAC) method, Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA), to allow multiple users to share a single communications channel. Note that this is not the MAC method used by Ethernet (it uses CSMA/CD), so it is a misnomer to call 802.11 technology wireless Ethernet.

Notes

If you upgrade your 802.11 base stations to 802.11b, they will still support legacy 802.11 clients—but only at their maximum data rate of 2 Mbps, which in actual practice is more like 1 Mbps.

For secure wireless transmission, data needs to be encrypted. The most popular solution is Wired Equivalent Privacy (WEP), which now is included as a standard feature with most wireless network interface cards (NICs), PC cards, and access points.

802.11a

An Institute of Electrical and Electronics Engineers (IEEE) wireless networking communications standard that supports data transmission rates of up to 54 megabits per second (Mbps). 802.11a is widely seen as the successor to 802.11b.

Overview

The 802.11a standard uses the same Media Access Control (MAC) layer mechanism as the more commonly deployed 802.11b, namely Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA), which allows multiple users to share a single channel at the same time. The encoding scheme used at the physical layer differs, however, because 802.11b uses the same physical-layer (PHY) encoding scheme as Ethernet, but 802.11a uses a different scheme: Coded Orthogonal Frequency Division Multiplexing (COFDM or Coded OFDM).

The frequency bands used by 802.11a also differ from 802.11b, because 802.11b uses the 2.4 GHz Industrial, Scientific, and Medical (ISM) band for its operation, and 802.11a employs portions of the 5 GHz Unlicensed National Information Infrastructure (UNII) band recently allocated by the Federal Communications Commission (FCC).

A single 802.11a communications channel consists of a 20 megahertz (MHz)-wide block of frequencies divided up into 52 subchannels each 300 kilohertz (KHz) wide, 48 of which are used for carrying data, with the remaining 4 subchannels reserved for error correction. By encoding data using 64-level quadrature amplitude modulation (64QAM), a data rate of 1.125 Mbps per subchannel can be achieved, which translates into a maximum overall transmission speed of $48 \times 1.125 = 54$ Mbps. Due to the limitations of the MAC layer mechanism,

however, actual data rates are only about 70 percent of theoretical, so that sustained data rates for 802.11a are rarely above 35 Mbps. Nevertheless, these high attainable speeds are sufficient to enable 802.11a systems to support some types of broadband applications, including Web browsing and multimedia.

The frequencies used by 802.11a cover three 200 MHz blocks of the 5 gigahertz (GHz) band:

- **5.15 to 5.25 GHz:** This band supports five independent channels with a maximum power output of 50 megawatts (mW).
- **5.25 to 5.35 GHz:** This band also supports five independent channels but with a maximum power output of 250 mW for greater distance and penetration of building materials.
- **5.725 to 5.825 GHz:** This upper band is designed for outdoor communications, supports five independent channels, and a maximum power output of 1 watt.

Advantages and Disadvantages

The main advantage of 802.11a over 802.11b is the increased data rate. By way of analogy, 802.11a is to 802.11b as Fast Ethernet is to standard 10 Mbps Ethernet. In fact, both of these standards are sometimes referred to as wireless Ethernet, but this is a misnomer because they use CSMA/CA instead of Ethernet's Carrier-Sense Multiple-Access with Collision Detection (CSMA/CD) mechanism at the MAC layer.

Besides the higher data rates supported by 802.11a as compared to 802.11b, another advantage of 802.11a is that the COFDM encoding mechanism includes greater error correction, which means better recovery from multipath reflection.

Implementation

As a result of these differences in signal encoding mechanisms, 802.11b and 802.11a are incompatible standards. Devices using one standard cannot communicate with devices supporting the other standard. Yet because these two technologies operate at different frequency bands, they can be deployed together and overlap without interference. 802.11b is already widely

deployed in many corporate enterprises; the logical migration path to 802.11a is to deploy 802.11a in small pockets where it is most required and gradually extend this as needed.

Marketplace

Two vendors pioneering in 802.11a hardware include Radiata Communications (now owned by Cisco Systems) and Atheros Communications. Both vendors offer devices supporting 6, 12, 24, 36, 48, and 54 Mbps transmission speeds, with different rates being achieved by using different encoding mechanisms. Atheros also supports bonding two channels to achieve a theoretical maximum transmission rate of 108 Mbps, and other vendors are developing proprietary extensions to 802.11a that may boost speeds up to 155 Mbps.

Issues

Because of the higher frequencies used, 802.11a devices are not susceptible to the kind of electromagnetic interference, including interference from microwave ovens and cell phones, that plagues 802.11b devices. However, because of different governmental policies regarding allocation of frequencies in the 5 GHz band, interoperability issues exist for 802.11a technologies used in different parts of the world.

For example, in Europe the upper 100 MHz portion (5.725 to 5.825) is already allocated for other uses, limiting operation of 802.11a gear to only 10 clear channels instead of 15. The 802.11a standard is also incompatible with the competing HiperLAN/2 standard being developed in Europe, which also uses frequencies from the 5 GHz band. In Japan only the lower 100 MHz portion is unallocated, which allows only five channels for 802.11a to work with. Other countries and regions use portions of the 5 GHz spectrum for military or satellite communications purposes, limiting the capability of 802.11a devices within their borders.

802.11b

An Institute of Electrical and Electronics Engineers (IEEE) wireless networking communications standard that supports data transmission rates of up to 1 megabit

per second (Mbps). 802.11b is sometimes called wireless Ethernet, but this is a misnomer because the two technologies use different Media Access Control (MAC) methods.

Overview

The 802.11b standard was developed over a number of years by Lucent Technologies, Intersil Corporation, and other industry partners and ratified as an IEEE standard in 1999. It is the most popular and widely deployed wireless networking standard currently in use, though it may be superseded over the next few years by 802.11a, which supports higher data transmission rates.

802.11b is capable of supporting data transmission rates of 1, 2, 5.5, and 11 Mbps. The actual transmission rate used will depend on the distance between the client adapter (PC card or network interface card [NIC]) and access point (base transmitting station) and upon interference due to obstacles in the transmission path. In general, the further the distance from the base station, the slower the data rate. For directional antennae operating with clear line-of-sight in point-to-point transmission, the top speed of 11 Mbps can be sustained for distances up to about 10 miles (16 km). Within a building using omnidirectional antennae, however, devices may need to be within 100 feet (15 meters) in order to maintain their highest transmission rate. If a device exceeds this range, the transmission rate drops to the progressively lower levels until a sustained transmission rate can be successfully negotiated. Each data rate uses its own characteristic modulation scheme, such as Binary Phase Shift Keying (BPSK) for 1 Mbps transmission, Quadrature Phase Shift Keying (QPSK) for 2 Mbps, and so on.

Although the theoretical top transmission speed for 802.11b is 11 Mbps, in practice the media access control (MAC) layer mechanism (Carrier Sense Multiple Access with Collision Avoidance [CSMA/CA]) and protocol overhead reduce efficiency to 60-70 percent. The result is that data rates of more than 6 Mbps are rarely achieved and 4-5 Mbps is more common. Note that this is the total shared bandwidth for all 802.11b clients within the same service area (served by the same set of access points or base stations), so actual throughput may be much less when many clients are active. The 802.11b standard allows multiple users to share a single communications

channel at the same time by using the CSMA/CA method as its MAC layer protocol. The 802.11b standard supports Request to Send/Clear to Send (RTS/CTS) as a MAC enhancement for transmission in environments where coverage is distorted by obstacles and interference, but this mechanism adds significant overhead to the protocol, especially during the transmission of small packets.

The drawing shows a typical 802.11b packet. This consists of a 30-byte header containing information for addressing, sequencing, and frame control. This is followed by a data or payload section that may range from zero to 2312 bytes in length, followed by a 4-byte checksum trailer.

802.11b. Typical structure of an 802.11b packet.

As far as frequency and transmission method are concerned, 802.11b employs direct-sequence spread spectrum (DSSS) transmission over an 83-MHz-wide chunk of the

unlicensed 2.4 GHz Industrial, Scientific, and Medical (ISM) band of the electromagnetic spectrum, specifically the frequency band from 2.400 to 2.483 GHz. Because this frequency band overlaps with emissions from microwave ovens and some cell phones, proximity of these devices can affect the transmission speed achieved.

Under Federal Communications Commission (FCC) regulations, 802.11b provides 11 separate channels for communications. Theoretically, this means that the total maximum bandwidth for an 802.11b local area network (LAN) utilizing all channels would be $11 \times 11 \text{ Mbps} = 121 \text{ Mbps}$. In practice, due to interference between channels, a given service area can only support three simultaneous channels, which limits total available bandwidth to $3 \times 11 = 33 \text{ Mbps}$ in theory, or about 14 Mbps in practice once protocol overhead is factored in.

A typical 802.11b wireless LAN segment may support up to 65 different clients, but the contention involved in the CSMA/CA media access method means that one busy client downloading a large file can utilize the segment's entire available bandwidth, leaving the other stations unable to communicate. Adding additional access points to the service area provides fault tolerance and load balancing but does not increase the total available bandwidth.

Implementation

When deciding whether you should immediately deploy 802.11b equipment in your enterprise or wait for the faster 802.11a to gain greater vendor support, you have several issues to consider. Small- and mid-sized companies might find 802.11b a cheap, easy, turnkey solution to deploy and might not need the higher data rates of 802.11a. And although both systems can be deployed in parallel, 802.11b equipment cannot be upgraded to 802.11a. Dual-radio access points are under development, but their deployment is complicated by the two standards' different transmission characteristics. Finally, enterprise architects may want to wait for 802.11a products that are certified by the Wireless Ethernet Compatibility Alliance (WECA) before committing large portions of their budget to a massive rollout of 802.11a.

Marketplace

More than 20 different vendors sell 802.11b-compliant hardware, and the standard's success is evident in the high degree of interoperability between equipment supplied by different vendors. A client network adapter (NIC or PC card) from one vendor is likely to work well with an access point (base station hub) from a different vendor without needing any modifications. Access points from different vendors are less likely to work together, particularly if they need to be configured for roaming users that move from one service area (cell) to another and require seamless networking during the transition. So the best solution is still to purchase all of your 802.11b devices from the same vendor in order to achieve the highest level of interoperability, particularly in large, geographically dispersed deployments with multiple access points spanning multiple subnets.

As a result of increased competition, prices for 802.11b equipment have fallen drastically of late. Client adapters are now available for \$99 or less, and access points can be had for under \$299. Some popular vendor products include

- **3Com Corporation:** AirConnect PC card and companion AirConnect Wireless Access Point designed for the enterprise, which supports Mobile IP and Microsoft Point-to-Point Encryption
- **Apple Computer:** AirPort client adapter and companion AirPort access point, a bargain system designed for Small Office Home Office (SOHO) environments and including Ethernet and V.90 modem support
- **Intel Corporation:** PRO/Wireless LAN PC card and companion PRO/Wireless LAN Access Point, with integrated Web server and 128-bit Wired Equivalent Privacy (WEP) support. Intel also recently acquired Xircom, which makes a wireless Ethernet adapter that is popular with Notebook users and supports 40- and 120-bit WEP.

Issues

While the maximum allowed power output for an 802.11b-compliant device is 1 watt, most 802.11b-compliant NICs and PC cards emit only about 30 milliwatts (mW) to conserve battery life in laptops and avoid excessive heat

dissipation. This is generally considered too low to constitute any health hazard to individuals using this equipment—for comparison, a typical cell phone may generate an electromagnetic power output of half a watt or more.

Notes

For an explanation of the different components needed in the deployment of a wireless network and how they operate, see the article “wireless networking” elsewhere in this book.

Do not operate 802.11b devices in an aircraft during flight—turn your device off when boarding. The signals transmitted by your device could adversely affect the aircraft’s electronic systems.

Look for the “WiFi” seal of approval on vendor packaging of 802.11b equipment. This designation indicates that the vendor’s equipment is approved by WECA as being fully compliant with 802.11b standards.

Wireless networks based on 802.11b can be susceptible to electromagnetic interference produced by microwave ovens, particularly if the clients are located far from the base station. If this occurs, move the oven, move the client adapter, or increase the transmission strength of the access point until you can achieve reliable communications.

To conserve power, especially for 802.11b PC cards in laptops, these client adapters should be set to run in Polled Access Mode (PAM). Clients configured for PAM go to sleep when not communicating with the base station and wake up according to a predefined schedule to check for an inbound Traffic Information Map (TIM) packet from the base station indicating that it has data ready to send the client. PAM typically uses about 10 percent of the power consumed when running in Constant Access Mode (CAM), where the client is always listening.

If your buildings have metal floors, wireless networking using 802.11b systems may not operate beyond 100 feet (30 meters) due to signal absorption. In such buildings you may also require an access point on each floor.

802.11b and Bluetooth devices operate on the same frequencies, so using both systems in the same service area may cause dropouts and transmission errors to occur.

802.12

The Institute of Electrical and Electronics Engineers (IEEE) standards outlining the architecture and operation of the Demand Priority Media Access Control (MAC) method. This access method is employed by the legacy 100VG-AnyLAN technology developed in 1994 by Hewlett-Packard and AT&T. The IEEE 802.12 working group is presently in hibernation and is no longer active.

802.13

The Institute of Electrical and Electronics Engineers’ (IEEE’s) Project 802 includes a number of standards and working groups relating to networking. These standards and working groups currently range from 802.1 through 802.17, but for some reason 802.13 was not used.

802.15

A set of standards being developed by the Institute of Electrical and Electronics Engineers (IEEE) for Wireless Personal Area Networks (Wireless PANs or WPANs).

Overview

The 802.15 working group is currently divided into a number of Task Groups (TGs) that are actively working on different aspects of wireless PANs. These TGs include

- **TG1:** This group is working to develop standards for WPANs based on Bluetooth 1.x wireless technologies.
- **TG2:** This group is trying to get 802.15 WPANs to coexist with 802.11 WLANs by overcoming issues

related to electromagnetic interference between the two technologies.

- **TG3:** This group is trying to develop High Rate (HR) WPANs with speeds in excess of 20 megabits per second (Mbps).
- **TG4:** This group deals with developing Low Rate (LR) WPANs with speeds in the range of 10–200 kilobits per second (Kbps). These LR WPANs will be used for things such as home automation, remote control, interactive toys, sensors, and similar systems.

802.16

A set of emerging Institute of Electrical and Electronics Engineers (IEEE) standards being developed for fixed broadband wireless networking.

Overview

Broadband wireless, also called Wireless MAN (WMAN), involves wireless high-speed data transmission between fixed points at various frequency bands. In other words, 802.16 is to the metropolitan area network (MAN) what 802.11 is to the local area network (LAN): similar technology but operating at higher speeds and over longer distances. WMAN is the wireless equivalent of broadband wired technologies such as Digital Subscriber Line (DSL).

The IEEE working group on 802.16 is subdivided into a number of Task Groups (TGs) to work at these different frequencies, specifically:

- **TG1:** This group is working on air interfaces in the 10–66 gigahertz (GHz) region of the electromagnetic spectrum.
- **TG2:** This group is working on ensuring coexistence between different wireless broadband access systems.
- **TG3:** This group is working on air interfaces in the 2–11 GHz region of the spectrum.

- **TG4:** This group is working on the Wireless High-Speed Unlicensed Metropolitan Area Network (Wireless HUMAN) standard, which involves transmission in license-exempt portions of the spectrum in the 5–6 GHz range.

1000BaseCX

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 1000 megabits per second (Mbps) Ethernet (that is, Gigabit Ethernet, or GbE) over shielded twisted-pair (STP) cabling.

Overview

The CX in 1000BaseCX stands for short-haul copper and indicates that this version of GbE is intended for short cable runs over copper cabling. 1000BaseCX technologies are in the beginning stages of being widely implemented in enterprise-level networks and are primarily used for collapsed backbones and high-speed interconnects within wiring closets and equipment rooms. 1000BaseCX and other GbE standards are defined in the 802.3z series of standards of Project 802 developed by the IEEE.

Implementation

1000BaseCX is to some degree simply an extension of standard Ethernet technologies to Gigabit-level network speeds. 1000BaseCX is implemented using STP cabling. This STP cabling must be standard 150-ohm balanced cabling and should have a quality slightly better than IBM Type I cabling. Cable segments can have a maximum length of only 82 feet (25 meters).

1000BaseCX. A typical 1000BaseCX network.

Like other forms of GbE, 1000BaseCX employs 8B/10B coding with a transmission frequency transmission of 1.25 GHz. 1000BaseCX is intended mainly for connecting high-speed hubs, Ethernet switches, and routers together in wiring closets. Common implementations for 1000BaseCX are in switch-switch and switch-server connections, with switch-server connections being the most frequently implemented use for 1000BaseCX.

1000BaseLX

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 1000 megabits per second (Mbps) Ethernet (that is, Gigabit Ethernet, or GbE) over fiber-optic cabling.

Overview

The *LX* in 1000BaseLX stands for long and indicates that this version of GbE is intended for use with long-wavelength (1300 nm) laser transmissions over long cable runs of fiber-optic cabling. 1000BaseLX technologies are in the beginning stages of being widely implemented in enterprise-level networks and are primarily used for long cable runs between pieces of equipment on a campus or within a building. 1000BaseLX and other GbE standards are defined in the 802.3z standards of Project 802 developed by the IEEE.

Implementation

1000BaseLX can be implemented using either single-mode fiber-optic cabling or multimode fiber-optic cabling. Transmission requires two optical fibers due to the full-duplex operation of 1000BaseLX. Cable segment lengths depend on the cable grade used, as shown in the table on the following page.

1000BaseLX. A typical 1000BaseLX network.

Cable Segment Lengths

<i>Cable Grade</i>	<i>Maximum Segment Length</i>
10-micron single-mode fiber	10 kilometers (6.2 miles)
50-micron multimode fiber	550 meters (1800 feet)
62.5-micron multimode fiber	440 meters (1440 feet)

1000BaseLX is intended mainly for connecting high-speed hubs, Ethernet switches, and routers together in different wiring closets or buildings using long cabling runs. 1000BaseLX is most commonly implemented in a switch-switch configuration.

Notes

When you use multimode fiber-optic cabling in 1000BaseLX implementations, a condition called differential mode delay (DMD) can sometimes occur. This condition occurs only in cabling of uneven quality, and it leads to signal jitter that can disrupt network communications. To resolve this problem, newer 1000BaseLX transceivers condition the signal to distribute its power equally among all transmission modes of the cable.

1000BaseSX

An Institute of Electrical and Electronics Engineers (IEEE) standard for implementing 1000 megabits per second (Mbps) Ethernet (that is, Gigabit Ethernet, or GbE) over fiber-optic cabling.

Overview

The *SX* in 1000BaseSX stands for short and indicates that this version of GbE is intended for use with short-wavelength (850-nanometer) laser transmissions over short cable runs of fiber-optic cabling.

1000BaseSX technologies are in the beginning stages of being widely implemented in enterprise-level networks and are primarily used for shorter cable runs between pieces of equipment within a building.

1000BaseSX is an extension of standard Ethernet technologies to gigabit-level network speeds. 1000BaseSX and other GbE standards are defined in the 802.3z standards of Project 802 developed by the IEEE.

Implementation

1000BaseSX is implemented using only multimode fiber-optic cabling. Cable segment lengths depend on the cable grade used, as shown in the table.

Cable Segment Lengths

<i>Cable Grade</i>	<i>Maximum Segment Length</i>
50-micron multimode fiber	500 meters (1640 feet)
62.5-micron multimode fiber	220 meters (720 feet)

1000BaseSX is intended mainly for connecting high-speed hubs, Ethernet switches, and routers together in different wiring closets or buildings using long cabling runs. 1000BaseSX is most commonly implemented in a switch-switch configuration.

Notes

When multimode fiber-optic cabling is used in 1000BaseSX implementations, a condition called differential mode delay (DMD) can sometimes occur. This condition occurs only in cabling of uneven quality, and it leads to signal jitter that can disrupt network communications. To resolve this problem, newer 1000BaseSX

transceivers condition the signal to distribute its power equally among all the cable's transmission modes.

1000BaseT

An Institute of Electrical and Electronics Engineers (IEEE) standard for a form of Gigabit Ethernet (GbE) involving transmission over copper cabling.

Overview

The *T* in 1000BaseT identifies it as operating over twisted-pair copper cabling and makes it an extension of the traditional 10BaseT and 100BaseT Ethernet technologies for transmission over unshielded twisted-pair (UTP) cabling. 1000BaseT is based on the IEEE 802.3ab standard and is intended to provide the simplest upgrade path for legacy 10BaseT and 100BaseT Ethernet networks.

1000BaseT is implemented using the commonly installed Category 5 (Cat5) cabling or enhanced Category 5 cabling version of UTP cabling. Cable segments for 1000BaseT must have a maximum length of 328 feet (100 meters). Category 6 (Cat6) cabling is expected to provide enhanced transmission characteristics for 1000BaseT networks when it becomes available.

1000BaseT uses all four pairs of wires in standard UTP cabling, as opposed to the two pairs of wires used in 10BaseT and 100BaseT networks. Using all four pairs of wires brings certain problems because of attenuation, crosstalk, and echoes arising from full-duplex transmission over single wires. Full-duplex transmission is used to enable each pair of wires to simultaneously transmit and receive data at a rate of 250 megabits per second (Mbps). The resulting four pairs of wires means that the total data rate is $4 \times 250 = 1000$ Mbps or 1 Gbps. Although each pair of wires carries data at 250 Mbps, the signaling is only at 125 Mbps. This is accomplished by using five-level pulse amplitude modulation (PAM) as the line coding mechanism, which encodes two bits of information for each signal pulse. The reason for this choice is that Cat5 cabling works well up to 125 megahertz (MHz) in standard installations.

1000 BaseT has been standardized by the IEEE under the 802.3ab specification since June 1999. This specification provides for the implementation of automatic link negotiation so that problems such as crossed cables can be detected and corrected for, that 100 Mbps interface can be detected and accommodated when connected to 1000BaseT ports, and that half-duplex network interface cards (NICs) and hub/switch ports can be recognized and used when detected. The standard also specifies special filters for hybrid circuits used in full-duplex transmission over single wires, a special five-level PAM encoding mechanism instead of binary signals, forward error correction techniques, and pulse shaping technologies to make 1000BaseT a functional and reliable networking technology.

Implementation

One popular use for 1000BaseT (also referred to as GbE over copper) is in wiring closets of enterprise networks. 1000BaseT GbE switches can be used to aggregate Fast Ethernet workgroup switches by first connecting the workgroup switches to 100/1000 Mbps ports on the GbE switches using Cat5 cabling and then uplinking the GbE switches to the network's GbE backbone switches using fiber.

1000BaseT. A typical 1000BaseT network.

Another growing use for 1000BaseT GbE switches is for connecting high-performance multimedia workstations and Web server clusters to the network backbone. The main limitation for 1000BaseT workstations is that they must be located within 100 meters of the switch. For interbuilding GbE links you need to use fiber. Note, however, that 1000BaseT only supports cable runs up to 328 feet (100 meters) in length, which means that you may need to modify existing cabling infrastructures in some large buildings when migrating from Fast Ethernet to 1000BaseT. Despite the potential application for supporting high-performance workstations, the most popular uses for 1000BaseT remain for backbone uses such as installing vertical risers between floors and horizontal cable runs between wiring closets, for interconnecting workgroup switches, and for connecting server farms and clusters to backbone switches.

Marketplace

Adapting the Ethernet standard to transmission at rates of 1 Gbps over existing Cat5 wiring means lower costs for companies planning to upgrade their switched backbones from 100 Mbps Fast Ethernet to GbE. A typical 1000BaseSX fiber port costs about 50 percent more than a comparable 1000BaseT copper port, so considerable cost savings can be achieved by implementing GbE over copper instead of fiber. However, copper is more susceptible to noise than fiber for gigabit transmission, and Cat5 cabling must be of the highest standard and deployed according to standards to ensure maximum reliability.

1000BaseT solutions are beginning to be implemented for short, high-speed interconnects within wiring closets in enterprise networks, for consolidating server farms in data centers, and for interconnects in carrier colocation sites. Some also envision using it for connecting high-performance workstations as well. Vendors of 1000BaseT equipment include Cisco Systems, 3Com Corporation, Hewlett-Packard, Asante Technologies, Nortel Communications, Extreme Networks, Intel Corporation, and Foundry Networks. Cisco's Catalyst 6500 for its Catalyst 6506 switch chassis module provides 16 1000BaseT ports and is popular with Internet service providers (ISPs) deployed at carrier colocation sites because of its fault-tolerant load balancing and realtime code upgrade capabilities. Foundry's

eight-port 1000BaseT modules for its BigIron 8000 switch chassis is another popular choice with excellent performance.

A number of vendors are also providing 1000BaseT NICs for use in high-speed servers and high-performance networks connected to GbE backbones. These vendors include 3Com, Intel, Sun Microsystems, and SysKonnect. A popular choice in enterprise server farms is the SysKonnect 9822 64-bit 66 MHz PCI card, which comes in single-port and dual-port configurations. Alteon WebSystems also has a 10/100/1000BaseT NIC with support for auto-negotiation and jumbo frames.

Currently 1000BaseT is the fastest growing type of GbE being deployed in enterprise networks, because it leverages the investment of existing Cat5 cabling installations. In the second quarter of 2000, GbE over copper accounted for 25 percent of GbE port sales.

Notes

1000BaseT is also sometimes referred to as 1000BaseTX.

Before installing 1000BaseT switches in a building wired with older Cat5 cabling (as opposed to newer enhanced Category 5 [Cat5e] cabling), be sure to test the cabling using a cable tester to make certain the installation fully complies with IEEE TSB95 field specifications. Common reasons for existing wiring failing to support GbE are crosstalk caused by improper cable termination in punch-down block and wall plates. Hewlett-Packard and Fluke Corporation are two vendors that sell suitable cable test equipment. Also, be sure also to use high-quality Cat5e patch cables for connecting patch panels to switches in wiring closets and for connecting servers or workstations to wall plates in work areas.

3270

An information display protocol for IBM mainframe computers.

Overview

The 3270 protocol is a family of protocols that includes separate specifications for terminal display and printer output. The 3270 protocol enables text-based connection-oriented conversations to take place between centralized mainframe hosts and supported peripherals, including terminals, printers, and controllers. These conversations originally took place over dedicated serial transmission links between the terminal and the mainframe controller. For long-distance computing, transmission over private wide area networks (WANs) such as the IBM Global Network enabled mainframe

COBOL programmers to work from home instead of having to commute to the office.

Private WAN services such as IBM Global Networks have now been dismantled and replaced with the Internet, and Web-based access to mainframe hosts has led to the development of hardware-based and software-based emulators. A 3270 emulator is a device or program that enables a workstation to communicate with a mainframe as if it were a dedicated 3270 terminal. A typical 3270 software emulator might use ActiveX controls or Java applets to display the 3270 terminal interface running within a Web browser window. These controls or applets are downloaded from a Web server acting as an intermediary between the Transmission Control Protocol/Internet Protocol (TCP/IP) local area network (LAN) on which the workstations reside and the mainframe host's Systems Network Architecture (SNA) network. Web-based 3270 emulators are popular in many corporate intranets where they can help leverage the usefulness of legacy mainframes and enable offsite users to access mainframe databases through the Internet.

Notes

You can use Microsoft SNA Server to enable a Windows 2000 or Windows .NET Server network to access a mainframe's hierarchical SNA network. SNA Server accomplishes this by defining and assigning dependent 3270 Logical Units (LUs). SNA Server client software must also be installed on each Windows 2000, Windows XP, or Windows .NET Server client that uses these SNA Server LU services. The SNA Server client software enables communication between 3270 applications on the client and the SNA server that provides a gateway to the mainframe.

The original 3270 protocol transmits streams of clear text information. If you are running terminal emulation software on a remote workstation and accessing the mainframe over the Internet, you need to make sure you are using Secure Sockets Layer (SSL) or some other method of securing your transmission.

5250

An information display protocol for IBM AS/400 systems.

Overview

The 5250 protocol enables text-based connection-oriented conversations to take place between AS/400 hosts and supporting peripherals, including terminals, printers, and controllers. The 5250 protocol is a family of protocols that includes separate protocols for terminal display and printer output. AS/400 display sessions use 5250 data streams over Advanced Peer-to-Peer Networking (APPN).

Recent years have seen the proliferation of Web-based software for enabling local area network (LAN) workstations to access information on AS/400 hosts. These solutions are called terminal emulators and may be either hardware- or software-based. A typical 5250 emulator is an application that uses ActiveX controls or Java applets to display the 5250 terminal interface running within a Web browser window. Emulation controls or applets are downloaded from a Web server acting as an intermediary between the Transmission Control Protocol/Internet Protocol (TCP/IP) LAN on which the workstations reside and the AS/400 host.

Notes

Printer emulation is the ability to print locally from a workstation running a terminal emulator. In order for 5250 terminal emulators to support printer emulation, they must conform to the TN5250 Telnet protocol. Otherwise, workstations must print to a centralized printer attached to the AS/400.

Microsoft SNA Server supports both 3270 and 5250 sessions between Microsoft Windows clients and IBM mainframes and AS/400 systems.

The 5250 protocol transmits streams of clear text information, so if you are running terminal emulation software on a remote workstation to access your company's AS/400 over the Internet, you need to make sure you are using Secure Sockets Layer (SSL) or some other method for securing your transmission.

A+ Certification

A certification for computer service technicians from the Computing Technology Industry Association (CompTIA).

Overview

A+ Certification certifies service technicians for competency in troubleshooting, repairing, and installing stand-alone and networked PCs. A+ is an internationally recognized certification that identifies minimum competency for entry-level computer technicians, typically those who have a minimum of six months of practical hands-on and interpersonal support experience. The Association for Services Management International (AFSMI) and a number of prominent hardware and software vendors back the A+ Certification.

A+ Certification was created by CompTIA to benefit all groups involved in the recruiting and hiring process. Specifically, it has the following advantages:

- A+ benefits managers and recruiters by helping them identify trained, competent individuals to fill vacant positions.
- A+ benefits job seekers by identifying skills they need to learn and develop and by providing a recognizable career path for self-advancement and employment.
- A+ benefits educational institutions by providing goals and objectives for developing industry-relevant technical training programs.

The A+ exam consists of two parts: a core section covering general computer hardware and software that is not vendor-specific and a module covering Microsoft operating system technologies for MS-DOS and Microsoft Windows platforms.

A record

A Domain Name System (DNS) record mapping a host name to an Internet Protocol (IP) address.

Overview

Also known as Address records, A records are the most common type of DNS records in name server databases. A records are used to resolve queries where host names need to be translated into IP addresses in order to establish network communications with the target host.

Examples

A typical A record looks like this:

```
MARGE    IN      A      172.16.22.155
```

Here, MARGE is the friendly name of the host, IN indicates the record is part of the Internet family (the default), A indicates the type of resource record (address record), and the IP address for MARGE is last.

See Also: DNS, resource record (RR)

A6 record

A Domain Name System (DNS) record for identifying Internet Protocol version 6 (IPv6) hosts on a network.

Overview

The A6 record is used to map a host's name to its 128-bit IPv6 address. To use this record, a host on an IPv6 network can query a name server by specifying the name of a target host, and the name server responds to the query by returning the IPv6 address of the target host. The "A" in A6 stands for address.

Examples

If the name of a host is BART and the IPv6 address is 3dd4:2500:12af:0302:edef:6d52, then the A6 record would be

```
BART      3dd4:2500:12af:0302:edef:6d52
```

Notes

A6 records are supported on BIND version 9.

AAA

Sometimes called triple-A; stands for Authentication, Authorization, and Accounting, a security framework for controlling access to network resources.

Overview

The three components of an AAA system are the following:

- **Authentication:** This is the process by which users are identified as being entitled to access specific network resources.
- **Authorization:** This process determines the level of access a user has to a specific resource.
- **Accounting:** This process determines which resources are being used and who uses them.

An AAA Server is a server providing authentication, authorization, and accounting services for a network. In a typical AAA implementation, users connect to an access server (for example, a Cisco router) using an authentication protocol such as Password Authentication Protocol (PAP) or Challenge Handshake Authentication Protocol (CHAP). The access server then interacts with the AAA server; for instance, Cisco Secure using security protocols such as Kerberos, Remote Authentication Dial-In User Service (RADIUS), or Terminal Access Controller Access Control System (TACACS). Cisco AAA protocols can then be configured on the access server using Internetwork Operating System (IOS) and applied to a particular interface.

AAAA record

Sometimes called quad-A, a Domain Name System (DNS) resource record that helps transition networks from Internet Protocol (IP) to IPv6.

Overview

The Internet Engineering Task Force (IETF) has developed several enhancements to DNS to help network managers migrate their IP networks to IPv6. These enhancements are outlined in RFC 1886. The AAAA record is one such item, and maps a 32-bit IP address to a newer 128-bit IPv6 address.

AAAA records are supported by Berkeley Internet Name Daemon (BIND) 4.9.5 and later. When networks are fully migrated to IPv6, AAAA records can be replaced by A6 records, which are supported in BIND 9.

Abilene

An advanced high-speed backbone network that was developed to support the Internet2 initiative.

Overview

Abilene was developed through a partnership between Cisco Systems, Nortel Communications, and Quest Communications and is a project of University Corporation for Advanced Internet Development (UCAID). Abilene's goal is to provide an advanced high-speed backbone for research and development testing of

advanced applications relating to Internet2 prior to their intended real-world deployment. To this end, Abilene provides a high-speed Synchronous Optical Network (SONET) and Internet Protocol (IP)-over-SONET backbone network that connects gigaPOPs (high-speed regional network aggregation points of presence) scattered around the world. For an administrative fee, universities and other institutions conducting Internet2 research can connect to Internet2 through Abilene's gigaPOPs for research and development purposes.

Abilene is wholly funded by university and corporate agencies affiliated with the Internet2 research project, but Abilene also supports the U.S federal Next Generation Internet (NGI) initiative and connects with the very high performance Backbone Network Service (vBNS) and other federal research networks.

absolute path

The hierarchical path that locates a file or folder in a file system starting from the root.

Overview

A file's absolute path enables that file's location to be precisely specified, independent of where the user's current directory is located. In Microsoft Windows, a file's absolute path is specified starting with a drive letter, followed by the hierarchy of directories in which the file is contained (with each directory separated by a backslash) and concluding with the exact filename. For example, on a computer running Windows Millennium Edition (Me), the absolute path to the executable for the game of Solitaire, which is typically located in the Windows directory on the C drive, would be the following:

```
C:\Windows\sol.exe
```

If the user opens a command prompt and the current directory is C:\Windows, the user can simply type `sol.exe` to run the Solitaire program. From any other current directory though, the user must either type the absolute path to execute the program, or specify the relative path from the current directory to the executable file.

On UNIX platforms, path names are specified using forward rather than backward slashes and absolute paths do not start with a drive letter. For example, the absolute path to the file `script12`, located in the `/bin` subdirectory of the `/usr` directory, would be

```
/usr/bin/script12
```

Abstract Syntax Notation One (ASN.1)

A standard from the International Standards Organization (ISO) that provides a mechanism for encoding human-readable symbols into condensed binary form.

Overview

Abstract Syntax Notation One (ASN.1) is a standard with several real-world uses:

- In X.400, it provides a standard way of formatting and encoding X.400-based e-mail messages for transmission over a network.
- In Simple Network Management Protocol (SNMP), the Management Information Base (MIB) is specified in ASN.1 notation.

More generally, ASN.1 is a method of specifying abstract objects that are intended for any form of serial transmission. ASN.1 is also used for defining objects in MIB files for SNMP.

ASN.1 is similar in syntax to a programming language, and it allows the definition of different data types, data structures, arrays, classes, and other structures similar to those found in the C++ programming language. The presentation layer (Layer 6) of the Open Systems Interconnection (OSI) reference model uses ASN.1 as the standard for specifying the syntax of information exchanged between applications at this layer. ASN.1 data types can be either simple or structured. An example of a definition of a simple data type and its value might be

```
EmployeeAddress ::= ISO646STRING      "99  
Microsoft Way"
```

A more complex structured data type might be

```
EmployeeRecord ::= SET
{
  name      [0]ISO646STRING  "Bob Smith"
  title     [1]ISO646STRING  "Support Specialist"
  idNumber  [2]INTEGER       "116427"
}
```

ASN.1 data structures are encoded as octets in hexadecimal notation. These structures are then transmitted over the network as binary information.

Notes

Microsoft Exchange Server uses ASN.1 for its X.400 Connector to provide standards-based connectivity with foreign X.400 messaging systems.

acceptable use policy

A policy created by management to specify acceptable usage for corporate network services as well as the consequences of violating these standards.

Overview

Acceptable use policies have lately become an important feature of corporate IT (information technology) culture for a number of reasons, but mainly because of the widespread implementation of Internet access for desktop users. Management often becomes concerned about the possibilities of employees surfing the Internet for personal use on company time, using company e-mail to send personal messages, sending spam or mail bombs, and so on. Another concern is management's possible legal liability if employees should access illegal or pornographic material on the Internet using their corporate Internet accounts.

Even if a company does not provide desktop Internet access for its employees, it should still have an acceptable use policy governing access to shared network resources such as file servers and color laser printers. To be effective, an acceptable use policy needs to have the following characteristics:

- Acceptable and unacceptable usage must be simply and clearly explained in the policy.
- A graded series of consequences of unacceptable usage must be clearly stated in the policy.
- The policy itself must be clearly visible in employees' work areas.
- Management should regularly call employees' attention to the policy.

In addition, users should be informed if management is utilizing monitoring practices such as logging all employee Internet access or archiving all employee e-mail. Management should consult its legal department in the drafting of an acceptable use policy, and this policy should be reviewed frequently and kept up-to-date as corporate network access evolves.

access

Generally, the process of connecting to and using resources on a network.

Overview

To provide a user with access to network resources, permissions must first be granted to the user. For example, if a user is granted the read permission (and only this permission) for a file on the NTFS file system (NTFS), the user is said to have read-only access to the file. An important part of a network administrator's job is to configure appropriate levels of access control—that is, to manage access to network resources such as shared files, printers, and applications so that

- Users who need access to these resources have the appropriate level of access to them
- Users who do not need access to the resources—as well as distrusted users or hackers—are prevented from accessing them

Examples

In Microsoft Windows 2000, when a user or process attempts to access an object such as a file on an NTFS volume, a component of the Windows 2000 operating

system called the Security Reference Monitor compares the access token attached to the process with the access control list (ACL) attached to the object. Through this comparison, the Security Reference Monitor determines whether to grant access to the user or process.

access control

Any mechanism that controls who can access securable objects and what actions they can perform on them.

Overview

Securable objects are objects whose access can be controlled by an operating system. For example, in Microsoft Windows 2000, Windows XP, and Windows .NET Server, the following are a few of the types of objects that can be secured:

- File system objects such as files and directories
- Service objects (installed services)
- Printer and print server objects
- Registry keys
- Shared directories
- Directory service objects in Active Directory directory service
- Objects exposed to Windows Management Instrumentation (WMI)
- Security provider objects
- Kernel objects such as processes, threads, jobs, semaphores, events, mutexes, named pipes, access tokens, and such

Access control consists of those mechanisms used to control access to the various types of securable objects listed above. In Windows 2000, Windows XP, and Windows .NET Server, access control is performed mainly through the assignment of permissions and rights.

Permissions are assigned to an object to determine who can access that object and at what level. Permissions can be set by an administrator or by the owner of the

object. The kind of permission that can be applied depends on the type of object. Some of the objects to which permissions can be applied include

- NTFS file system (NTFS) objects such as files, folders, and volumes
- Local system objects such as processes and programs
- Local or Active Directory objects such as user, group, and printer objects

The issue of inheritance is related to permissions. When permissions are assigned to a folder on an NTFS volume, they are also inherited by default by all existing child folders and files within the folder, and by any new child folders or files created later. Similarly, when permissions are assigned to a container in Active Directory, they are also inherited by default by all existing child objects within the container and by any new child objects created later.

Rights are assigned to user or group accounts to provide them with authorization to perform a specific system task, such as backing up a volume, shutting down the system, or logging on to the console interactively. Rights are most often assigned to groups rather than individual users to simplify administration. Rights can be specified at either the local or domain level.

Another aspect of access control is the issue of *ownership*. When a user creates an object in Active Directory or a file on an NTFS volume, that user becomes the owner of that object or file. The owner has the right to set and modify the permissions of the object. Every object in Active Directory and every file or folder on an NTFS volume has an owner.

One additional aspect of access control is the issue of *auditing*. Files and folders on an NTFS volume can be audited to keep track of failures or successes in accessing them. This can be important in detecting security breaches in your network.

Notes

When assigning permissions to objects in Active Directory, you can assign them either to the object itself (and therefore to all its attributes) or to specific attributes of

the object. For example, you could allow all users to have read access to the Phone Number attribute of users in Active Directory, while granting the clerical group read/write access to that attribute so that they can modify users' phone numbers if necessary.

access control entry (ACE)

A single entry in an access control list (ACL).

Overview

An access control entry (ACE) is part of an ACL applied to an object, and it contains information that is used to control that object's access. Both discretionary access control lists (DACs) and system access control lists (SACLs) consist of sequential lists of ACEs. For example, an ACE could specify the access or auditing permissions to an object in Active Directory directory service or on a volume formatted using the NTFS file system (NTFS) for a particular user or group.

ACE	
SID 012345	
✓ Read	
✗ Write	
✓ Execute	
.	
.	
.	
✗ No Access	

Access control entry (ACE). A simplified example.

An ACE generally specifies two kinds of information:

- The security identifier (SID) of the security principal (user, group, or computer) to which the ACE applies
- The level of access to the object permitted for that security principal

An access mask specifying the possible permissions that can be assigned to the object is included with each ACE. An ACE can provide one of the following:

- Discretionary access control for explicitly granting or denying access to a specific user or group (AccessAllowed and AccessDenied entries)
- System security access control for generating security audit logs (SystemAudit entry)

access control list (ACL)

Any mechanism for implementing access control on a file system object, directory object, or other operating system object.

Overview

Access control lists (ACLs) are a feature of most operating systems and provide a flexible and granular method for securing different operating system objects. This article will look at two examples of ACL implementations: Microsoft Windows 2000 and Sun Microsystems' Solaris operating system.

ACLs are incorporated into the basic operating system architecture of Windows 2000 and Windows NT operating system platforms and are used to control access to objects in Active Directory directory service as well as files on NTFS file system (NTFS) volumes. An ACL is basically a list attached to an object specifying which security principals (users, groups, computers, and so on) are allowed to access the object and what level of access they are allowed to have.

In Windows 2000, ACLs are more properly called discretionary access control lists (DACs) because administrators can configure and manage them at their discretion. There's also another type of ACL in Windows called a system access control list (SACL), which is used to control the generation of audit messages when object auditing has been configured on a file system.

In traditional UNIX environments, access to file system objects is controlled using the Chmod (change mode) command, which allows read, write, and execute permissions to be allowed or denied for three different entities: the user (owner), the other users that belong to the same group as the user (group), and every other user on the system (other). This permission-based access control mechanism is extremely limited, and as a result most UNIX

systems implement ACLs as an alternative method for securing files and other operating system objects.

Sun's UNIX-based Solaris operating system first implemented ACLs in version 2.5.1. These ACLs can be used to control access to files on various different file systems, including:

- **UNIX File System (UFS)**
- **Network File System (NFS) version 2 and higher**
- **Loopback File System (LOFS)**
- **Cache File System (CacheFS)**

In Solaris, ACLs can be applied to files, directories, and symbolic links, and default permissions can be defined for directories to give all newly created files in the directory the same ACLs. To set and display access control lists on Solaris, use the `setfacl` and `getfacl` commands.

ACLs are also available as third-party software for other UNIX platforms. Other UNIX packages and add-ons may use different commands such as `setacl` and `getacl`.

Accessibility Options

A utility in Control Panel for most versions of Microsoft Windows that allows you to adjust the behavior of the keyboard, mouse, and display to suit the needs of individuals with impaired eyesight, hearing, or motor skills.

Overview

Accessibility Options are part of Microsoft Corporation's initiative to provide access to computer technology to all individuals, regardless of their physical impairments. Settings for Accessibility Options include the following:

- **StickyKeys:** Makes it possible to use a key combination such as Ctrl+Alt+Delete without pressing more than one key at a time
- **FilterKeys:** Makes it more difficult to bounce keys by telling the system to ignore brief or repeated keystrokes

- **ToggleKeys:** Generates sounds when certain toggle keys, such as Caps Lock, are turned on
- **SoundSentry:** Flashes a specified part of the screen when the system generates sounds
- **ShowSounds:** Displays icons or text captions to accompany the sounds that programs generate
- **HighContrast:** Makes reading text easier
- **MouseKeys:** Controls the pointer using the numeric keypad
- **SerialKey:** Enables the use of alternative input devices connected to the computer's serial port instead of the keyboard and mouse

Accessibility Options. Accessibility Options in Windows 2000.

Windows includes an additional wizard called the Accessibility Wizard that allows you to configure accessibility options on your computer. Additional accessibility utilities include Magnifier, Narrator, and On-Screen Keyboard.

Accessibility Wizard

A Microsoft Windows utility for configuring a computer for individuals with impaired visual or motor skills.

Overview

Accessibility Wizard is an alternative to Accessibility Options for configuring computers for individuals with disabilities. To start the Accessibility Wizard, choose Accessories from the Start menu. Then, from the Accessibility program group, choose Accessibility Wizard. Note that in Windows Millennium Edition (Me), you might have to install the Accessibility Tools to gain access to the wizard.

Accessibility Wizard. The Accessibility Wizard for Windows 98.

The wizard leads the user through a series of questions concerning his or her disability and configures mouse, keyboard, and display properties to meet that person's particular need. This tool gives administrators the ability to configure workstations for individuals with

physical impairments by leading the user through a series of screens that the user can then respond to in real time. Using the Accessibility Wizard is generally more convenient than using the Accessibility Options property sheet to configure accessibility settings. The wizard's final screen lists the accessibility options that have been enabled.

access list

A mechanism by which routers can determine which packets should be forwarded and which should be blocked.

Overview

Routers route packets to their destination by examining the destination address of packets received and then determining which port the packet should be forwarded to. However, sometimes packets should not be forwarded to their destinations at all or should be forwarded to different ports using criteria other than a simple destination address. For example, certain incoming packets may constitute a security hazard to the network and should be blocked and dropped. Load balancing may require that packets be distributed across multiple ports in round-robin fashion instead of delivered to a fixed address. And certain types of traffic have high priority and need special handling. Access lists are a mechanism for handling these issues and provide a packet filtering capability that enhances the power and functionality of routers.

An access list is basically an ordered (sequential) series of rules or filters, each of which either permits or denies the flow of packets across an interface depending on the rule's nature and the packet's contents. When a packet arrives at an interface on which an access list has been created and applied, the rules in the list are applied to the packet in order from the top of the list downward. If the packet's contents match the conditions in a rule, that rule is applied and the packet is either forwarded or dropped. If a rule does not apply, the next rule in the list is tried until either a match is found and the packet processed or the end of the list is reached and the packet is

finally dropped (in other words, there is an implicit “deny all” at the end of every access list).

You should consider several things when using access lists to filter packets through a router:

- For an access list to function, it must first be created in the router’s memory and then explicitly assigned to a router interface.
- When an access list is applied to an interface, the access list’s direction must be specified. That is, you must decide whether the access list will be applied to inbound traffic, outbound traffic, or both.
- The order in which the rules are organized within an access list is important. Two access lists with identical rules but in different order can have significantly different effects.
- Each rule either permits a matching packet to be forwarded or denies a packet from being forwarded.
- By default, an access list implicitly denies everything. In other words, when a packet is being processed by an access list, if a match occurs that allows the packet to be forwarded, the packet is allowed to pass across the interface. If no match is found (the contents of the packet do not explicitly match any of the criteria specified in the rules within the access list), the packet is blocked from passing over the interface and is thus dropped by the router.

Examples

The Internetwork Operating System (IOS) by Cisco Systems, the operating system used by all Cisco routers, has commands for creating access lists and applying them to an interface. IOS supports two different types of access lists:

- **Standard:** A standard access list filters packets based only on their source address.
- **Extended:** An extended access list filters packets based both on their source address and on a number of other criteria including destination address, protocol type, traffic priority, and application type.

A simple example of an IOS access list rule that allows traffic from source address 172.16.15.33 to pass across a specified interface would be

```
access-list 1 permit host 172.16.15.33
```

Here the number “1” specifies that this rule is part of the first access list created on the router, and all rules that have this number belong to the same list. Access list numbers identify what kind of access list is used (see the table).

Examples of Different Kinds of IOS Access Lists

<i>Type of Access List</i>	<i>Range of Access List Numbers</i>
Standard Internet Protocol (IP)	1–99
Extended IP	100–199
AppleTalk	600–699
Standard Internetwork Packet Exchange (IPX)	800–899
Extended IPX	900–999

To take another example, if your network is class C and has addresses belonging to the 172.16.44.0 network, to allow stations on your network to have unrestricted access to the Internet through your packet-filtering router, you could use the rule

```
access-list 1 permit 172.16.44.0 0.0.0.255
```

Note that 0.0.0.255 is the binary complement of the default subnet mask of your class C network (255.255.255.0).

As a final example, the following access list blocks incoming traffic from the malicious host 133.16.1.11 but allows all other traffic to enter through the router:

```
access-list 1 deny host 133.16.1.11 log
access-list 1 permit any
```

The *log* keyword specifies that all packets dropped from the malicious host will be logged in the router log and can be viewed using the IOS logging console.

IOS access lists can be created using a simple ASCII text editor and transferred to the router using Trivial File Transfer Protocol (TFTP) or some other mechanism. The Interface command is used to apply an access

list to an interface once the list has been created, and the Access-group command is used to specify the direction over the interface for which the list applies.

Notes

One limitation of IOS access lists is that if you want to modify a list by removing or changing a statement in the middle of the list, you cannot. Instead you must create a new access list, remove the old one from the interface, and apply the new list to the interface. You can, however, add rules to the bottom of an existing list, if this meets your needs. To get around having to create an access list from scratch when you need to modify a rule, use TFTP to copy the existing router configuration to a text file on a workstation, modify the file, delete the original configuration on the router, and copy the modified configuration onto the router.

IOS version 12 includes a new feature that allows for the creation and application of time-based access lists, which allows different access lists to be applied to routers at different times and days.

Access lists are sometimes called access control lists, but this can be confusing because the term *access control list (ACL)* also refers to a mechanism for securing file system objects and other operating system objects.

The table in this article shows that there can be only 100 possible access lists for each type of access list. In some circumstances (for example, with complex backbone routers) this is not sufficient, and you can use named access lists instead. Named access lists are referenced using an alphanumeric name instead of a number, and you can create as many of them as you need.

Placement is an important issue to consider when applying access lists to ports. Standard access lists should be placed as close as possible to the destination, but enhanced access lists should be placed as close as possible to the source.

access mask

A double-word value (32-bit entry) contained within each access control entry (ACE) that defines all possible access rights for a particular type of object (file, folder, and so on).

Overview

Microsoft Windows 2000, Windows XP, and Windows .NET Server use access masks that support several types of access rights. Three examples are:

- **Specific access rights:** These access rights include FILE_READ_DATA and FILE_APPEND_DATA, which provide permission to read and write data in a file. Objects can have up to 16 different specific access rights, depending on the object type.
- **Standard access rights:** These apply to all objects and include DELETE, which grants or denies delete access to an object, and WRITE_OWNER, which grants or denies access to the owner security identifier (SID) of an object.
- **Generic access rights:** These map to specific access rights and standard access rights. Each type of securable object maps generic access rights to its own specific and standard access rights. Generic access rights for file objects include FILE_GENERIC_READ, FILE_GENERIC_WRITE, and FILE_GENERIC_EXECUTE. These three types are listed in Windows Explorer in Windows 2000, Windows XP, and Windows .NET Server and in Windows NT Explorer in Windows NT as the special permissions read (R), write (W), and execute (X).

access method

Any method that allows devices to transmit signals over media in a way that ensures that communications can occur between stations.

See: *media access control method*

access mode

A mode of running a console created with the Microsoft Management Console (MMC).

Overview

Different access modes are provided for MMC consoles in order to allow or restrict access to administrative functionality. This enables senior administrators to create custom consoles for junior administrators that have only the functionality needed to perform specified tasks, while preventing them from using functionality that could cause problems if not handled correctly.

Selecting Options from the Console menu configures access modes for MMC consoles. The two modes available for running consoles are

- **Author mode:** This mode grants the user full access to all the functionality of the MMC, including adding snap-ins, removing snap-ins, creating new console windows, and accessing the entire console tree. Only senior administrators should have this access mode.
- **User mode:** This mode does not allow the user to add snap-ins to or remove snap-ins from the console and restricts access to some of the functionality of the MMC, depending on the options selected. For example, by selecting the Limited Access, Single Window option, the MMC displays only a single console window. User mode has three submodes:
 - **Full Access:** This submode allows the user to view the whole console tree but restricts the user from adding new snap-ins or changing the console's properties.
 - **Limited Access, Multiple Window:** This submode allows the user to view portions of the console tree in different windows.
 - **Limited Access, Single Window:** This submode restricts the user to a single console window.

Notes

If an MMC console is set to user mode, you can start it in author mode by running it from the command line

with the /a switch. You can also right-click on the console file (*.msc file) in Windows Explorer and use the shortcut menu to start the console in author mode. However, an administrator can also use Group Policy to prevent the user from opening a console in author mode.

access point (AP)

A device connected to a local area network (LAN) that enables remote wireless stations to communicate with the LAN.

Overview

A wireless networking implementation consists of two parts:

- A wired network such as an Ethernet LAN with an access point attached to it. The access point acts as a bridge between the wired LAN and the remote wireless stations.
- Remote wireless stations with wireless network adapters attached to them.

Access point (AP). *How an access point works.*

An access point (AP) is basically a network-capable device containing a transceiver and antenna for transmitting signals to and receiving signals from the remote stations. The access point thus provides a “point of

access” to the wired network for the remote stations. The access points allow wireless stations to be quickly and easily connected to a wired LAN.

An example of a remote station might be a laptop computer. The laptop can communicate with the access point using a wireless Personal Computer Memory Card International Association (PCMCIA) card or wireless network interface card (NIC). An alternative is the station adapter, a device that plugs in to the laptop’s standard 10BaseT port.

A single AP can generally support 15 to 25 wireless stations while still maintaining optimal data transfer rates. The area covered by a single AP is called a cell. The transceiver within an access point uses spread spectrum transmission, which may be either direct sequencing or frequency hopping. For spread spectrum communication in the 2.4 gigahertz (GHz) frequency band, APs typically support data rates of 1 to 3 megabits per second (Mbps) over distances of up to about 2 miles (3 kilometers).

Marketplace

Most commercial APs consist of a combination of an Ethernet port and a transceiver, which allows the AP to be easily connected into an existing wired LAN for bridging to remote wireless stations. Prices for wireless networking equipment based on the 802.11b standard have fallen dramatically in the last few years. A typical AP can cost as low as \$300 or as high as \$2,000, while wireless network adapters can be as low as \$100 each. Examples of APs for small-office home-office (SOHO) use include the Apple Airport, the D-Link DWL-1000AP, and the Lucent RG-1000, and examples of enterprise-class access points include 3Com’s AirConnect Wireless AP, the Cisco AIR-AP341 series, Enterasys’s RoamAbout AP 2000, and the Intel PRO/Wireless LAN AP.

The higher-priced APs provide faster speeds, support more users, and include better management features. For coverage of large areas, several APs may be required to create a pattern of overlapping cells—in this case it is best to purchase the more expensive ones because these include features to support remote sta-

tions that roam between cells covered by different APs. The more expensive APs also support connection to external antennas for better transmission coverage.

Many APs include other advanced features including Dynamic Host Configuration Protocol (DHCP), network address translation (NAT), and routing functions. These APs fall under the general category of network appliance because of their simplicity and ease of use.

Notes

When purchasing an 802.11b AP, you may want to consider if it can be easily upgraded to the newer 802.11a standard, which uses 5 GHz transmission.

For best coverage within an office environment, mount APs on ceilings. If this is difficult because of lack of electrical outlets, look for APs that can be powered over Category 5 (Cat5) cable.

If multiple APs are used to provide redundant coverage for an area, then they should be connected using a wired LAN. This will provide better performance for stations within the coverage area than having the APs connected as wireless repeaters.

access provider

Also known as Internet service provider (ISP), a company that provides individual users and businesses with connectivity to the Internet.

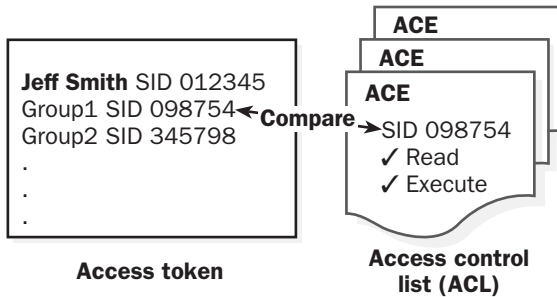

See: Internet service provider (ISP), xSP

access token

An object assigned to a user that successfully logs on to a network and that identifies the level of security privileges assigned to that user.

Overview

An access token is like a card key. Your card key will provide you with access to doors that have been configured to grant you permission to open them. The list of card keys that a door will accept is analogous to an access control list (ACL).

Access token. A simplified example of an access token at work.

When you log on to Microsoft Windows NT, Windows XP, Windows 2000, or Windows .NET Server, you are granted an access token that is attached to all your user processes. Your access token contains the security identifier (SID) of your user account and every group to which you belong. When your application tries to access an object such as a file on a volume formatted with the NTFS file system (NTFS), Windows NT, Windows 2000, Windows XP, or Windows .NET Server compares the SIDs in your application's access token to those in the access control entries (ACEs) in the object's ACL. If it finds a match, the system grants access to that object.

account

A set of credentials for gaining access to resources in a network or logging on to a system.

Overview

In a typical network, each user needs an account to access resources on the network, such as shared folders, printers, or applications. Accounts provide a way of identifying users on a network and are the foundation of network security. An administrator or another user with high security privileges typically creates accounts.

Accounts are generally used in server-based networks where a central computer such as a Microsoft Windows 2000 or Windows .NET Server domain controller keeps

track of each user's account and grants or denies access to the network based on the credentials entered by the user during the logon process. Accounts are used less frequently in peer-to-peer networks or workgroups because the security requirements are usually much less stringent.

A Windows 2000 or Windows .NET Server network contains various kinds of accounts, including

- **User account:** Identifies users who belong to the domain by storing their names, passwords, the groups they belong to, the permissions they have for accessing system resources, and other personal information
- **Group account:** Identifies a specific group of users and is used to assign them permissions to objects and resources
- **Computer account:** Identifies machines that belong to the domain

account domain

A type of Microsoft Windows NT domain containing accounts for global users and groups.

Overview

Account domains are usually master domains and are typically used in a single or multiple master domain model implementation of Windows NT. The account domain contains user accounts for every user in the enterprise and is usually located at corporate headquarters. Servers and workstations at company branch offices belong to other domains called resource domains. Users at branch offices who want to log on to the network must log on to the account domain, even though their workstations are located within a resource domain.

GOAXX06 (was GOAui06.bmp in 1E)

Account domain. Account domains in Windows NT.

For this scenario to work, a trust relationship must be established so that each resource domain trusts the account domain. In this way all user accounts can be centralized in the account domain, which eases account management for administrators located at headquarters.

Account domains simplify account administration by centralizing administration to a single domain.

account lockout

A condition in which a user is prevented from logging on to the network.

Overview

If account lockout restrictions are set on a network, a user who fails successively to log on will be locked out of the network after a predetermined number of attempts. For example, if a user forgets the password and repeatedly attempts to log on, the authentication provider (a domain controller on a Microsoft Windows 2000 network) assumes that unauthorized access is being attempted and shuts out the user by locking out the account. The account can either remain locked until an administrator unlocks it or it can be configured to unlock after a specified period of time.

Account lockout restrictions are typically part of the account policy that can be set for domains. Account

lockout is used to prevent unauthorized access to the network by preventing distrusted users from attempting to guess a trusted user's password. If you set up account lockout on your network, you will probably also want to configure auditing to record failed logon attempts.

Use account lockout only for high-security networks. In a low-security environment, users can become frustrated if they lock themselves out by mistyping their passwords, and administrators must cope with the additional overhead and bother of unlocking these accounts.

account operator

A user who is assigned the responsibility of administering user and group accounts for a network.

Overview

In Microsoft Windows 2000, Windows XP, or Windows .NET Server, if you want to make an individual an account operator, simply make that person a member of the Account Operators group. Account operators can administer accounts only on a domain controller, not on a member server or workstation.

Account operators have the preassigned rights to log on locally to a domain controller and to shut down the system. In addition, account operators have the built-in capacity to create and manage user accounts, global group accounts, and local group accounts, as well as to keep local profiles.

Account operators should be assigned in enterprise-level networking environments only. In small to medium-sized networking environments, creating and configuring user accounts is usually the administrator's responsibility.

See Also: *user account*

Account Operators group

A built-in security group in Microsoft Windows 2000, Windows XP, and Windows .NET Server where users are account operators.

Overview

Members of the Account Operators group can create, delete, and modify the properties of users, global groups, and local groups. The Account Operators group exists only on domain controllers and has an empty initial membership. The Account Operators group has the following preassigned rights:

- Log on locally
- Shut down the system

Additionally, members of the Account Operators group have the ability to create, delete, and modify user and group accounts using the Active Directory Users and Computers console.

Members of the Account Operators group cannot modify the membership or rights of the following built-in groups:

- Administrators
- Account Operators
- Server Operators
- Print Operators
- Backup Operators

ACE

Stands for access control entry, a single entry in an access control list (ACL).

See: *access control entry (ACE)*

ACK

Stands for acknowledgment, a transmission from a receiving station to a transmitting station telling it that the transmitted data has been received without errors.

Overview

ACKs play an important role in most network protocols. For example, Transmission Control Protocol (TCP) is a connection-oriented protocol that relies on acknowledgments for successful transmission of data. When a stream

of TCP packets is being sent over the network, each packet contains an acknowledgment number indicating the sequence number of the next packet that the receiving station should expect to receive. TCP can use an ACK to acknowledge a series of TCP packets (instead of just a single packet) that have been received. A TCP packet sent as an acknowledgment has its ACK flag set to 1 to indicate that the acknowledgment numbers of the packets received are valid.

During a transmission, if the receiving station determines that the data transmission is late or has not arrived, a negative acknowledgment (NAK) is generated to indicate to the transmitting station that the data should be sent again.

Active Desktop

A feature of Microsoft Windows that enables active content from Web sites or channels to be displayed directly on the desktop.

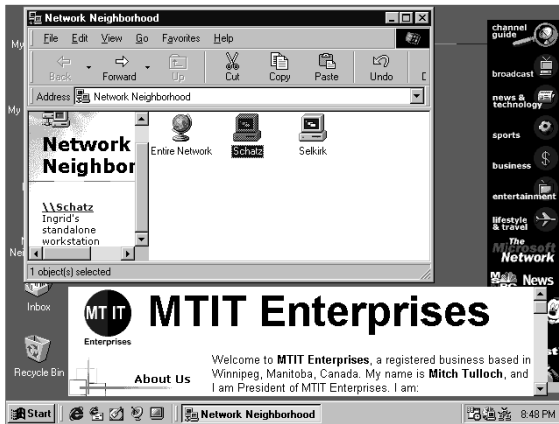

Overview

Active Desktop was first introduced with Microsoft Internet Explorer version 4, and made possible the dynamic downloading and display of content such as graphics, Hypertext Markup Language (HTML) pages, Microsoft ActiveX controls, Java applets, and channels. For example, you could have a stock ticker applet placed directly on your desktop that updates its information continually using a live Internet connection.

Active Desktop integrates the Web and your desktop, allowing you to launch programs, switch between files, and customize your desktop using active Web content. Active Desktop makes your desktop and its folders look and work like the Web, allowing you to browse resources on your computer or local network the same way you browse for content on the World Wide Web. Information about volumes, folders, and files can be displayed as Web pages within folders, and you can move up and down the folder hierarchy using a single click instead of a double click.

Active Desktop is included with Windows 98, Windows Millennium Edition (Me), Windows 2000, Windows XP, and Windows .NET Server and is available for Windows 95 and Windows NT 4 as an option by installing Internet Explorer 4 and the Windows Desktop Update.

The Active Desktop is implemented as an application programming interface (API) called the IActiveDesktop interface, which is part of the Windows Shell API. This interface is designed to allow client programs to manage desktop items and wallpapers on local computers. It also provides methods for adding desktop items (with or without a user interface, allowing the user to decide whether to accept the addition), adding desktop items associated with a Uniform Resource Locator (URL), applying changes by writing settings to the registry, and so on.

Active Desktop. Web elements on Active Desktop.

The Active Desktop consists of two layers:

- **HTML layer:** This is the background layer that hosts active Web content items. The Hypertext Markup Language (HTML) layer has three components: a file named `desktop.htm` that contains HTML tags for each active Web component on the desktop, an ActiveX control that lets you move or resize components on your desktop, and any other static HTML element you want to display in the background.
- **Icon layer:** This transparent foreground layer integrates a Web-type environment with familiar Windows 95 shell features such as double-clicking, drag-and-drop, file associates, and so on.

Users can add new items to the Active Desktop on their machines by using the display utility in Control Panel (or by right-clicking a blank area of the desktop and choosing Properties from the context menu). Either specify the URL of the object you want to add to your Active Desktop or browse to locate it on your network or on the Internet (if you are connected). Programmers can use the `ActiveDesktop` interface to write routines that add, remove, or modify items on the Active Desktop. You can also add items to the Active Desktop using a Channel Definition Format (CDF) file.

Active Digital Profile (ADPr)

An Extensible Markup Language (XML) specification for automating the provisioning of IT (information technology) resources.

Overview

XML is becoming the de facto standard for exchange of electronic information, superseding previous standards such as Electronic Data Interchange (EDI). To standardize exchange in different business areas, XML schema are used. Active Digital Profile (ADPr) is a proposed XML schema that allows for the electronic allocation and deployment of IT (information technology) resources such as hardware and software. As an XML schema, ADPr provides a vendor-neutral and platform-independent model for these business processes to take place at a high level.

ADPr is based on software created by Business Layers in conjunction with Novell, CheckPoint Software, and other companies. ADPr has been submitted to the Organization for the Advancement of Structured Information Standards (OASIS) as a proposed XML standard.

Active Directory

The directory service for the Microsoft Windows 2000 and Windows .NET Server network operating systems.

Overview

Active Directory directory service consists of both a database and a service. Active Directory is a database of information about resources on the network, such as computers, users, shared folders, and printers. It is also a service that makes this information available to users and applications.

Active Directory provides the basic features needed for an enterprise-level directory service, including an extensible information source, naming conventions for directory objects, a common set of policies, and tools for administering the service from a single point of access. Administrators can configure Active Directory to control access to network resources by users and applications. Active Directory provides network administrators with centralized administration of all

information about resources on the network, and it provides both users and administrators with advanced search capabilities for locating resources on the network.

Information in Active Directory is maintained for each domain on the network. Active Directory database information is stored and maintained on machines called domain controllers. This information is replicated automatically between domain controllers to ensure that every portion of the distributed directory is up to date. By default, the replication of updates to Active Directory occurs automatically every five minutes. Automatic replication of Active Directory information occurs only within the security boundary of a specific domain. Domain controllers in one domain do not automatically replicate with those in another domain.

Architecture

Active Directory's basic element is the object. An object can represent a user, computer, printer, application, file, or another resource on the network. Active Directory objects possess attributes, which are their properties. For example, some user attributes might include first name, last name, e-mail address, and phone number. Some attributes must have mandatory values, and others can be left undefined. A printer's attributes might include its location, its asset number for accounting purposes, its type, and so on. Active Directory also has a set of rules governing which objects can be stored in the directory and which attributes these objects can possess. This set of rules is known as the schema.

A special type of Active Directory object is the organizational unit (OU). An OU is a type of object that can contain other objects. An OU can either contain a specific object, such as a user or an application, or it can contain another OU. Using OUs, you can organize Active Directory into a hierarchical directory of network information based on the X.500 directory recommendations of the International Telecommunication Union (ITU). You can assign users permissions on subtrees of OUs for management and resource access purposes.

Organizational units are contained within domains, which are Active Directory's basic security and organizational structure. Every object in Active Directory must belong to a domain. Domains usually mirror the

organizational structure of your enterprise and act as a security boundary in it. For example, privileges granted in one domain are not automatically carried over to another domain. Domains can be joined into larger structures called trees using two-way transitive trusts, and these tree structures can be grouped into forests. Typically one forest is created per enterprise when Active Directory is deployed.

The collection of objects, OUs, domains, trees, and forests represent Active Directory's logical structure. Active Directory's physical structure consists of various layers of programming elements on servers called domain controllers. These programming elements include

- **Directory System Agent (DSA):** The process that provides access to the Active Directory store where directory information is stored on the domain controller's hard drive.
- **Database Layer:** This layer provides a uniform interface for the DSA for accessing the store.
- **Extensible Storage Engine (ESE):** This is a version of the database engine on Microsoft Exchange Server 5.5 and is used to provide access to the Active Directory store, which is capable of storing information about many millions of directory objects.

Above these layers are various interfaces and protocols by which various clients can access Active Directory. These include

- **Lightweight Directory Access Protocol (LDAP):** Supports LDAP clients such as Microsoft Outlook and Active Directory Services Interface (ADSI).
- **Replication transports (REPL):** Supports replication transports such as remote procedure call (RPC) and Simple Mail Transfer Protocol/Internet Protocol (SMTP IP) for Active Directory replication.
- **Security Accounts Manager (SAM):** Supports Windows NT 4 networking application programming interfaces (APIs) and replication with Windows NT backup domain controllers (BDCs).
- **Messaging Application Programming Interface (MAPI):** Supports Outlook and other MAPI-compliant clients.

Other protocols whose implementation is of crucial importance for Active Directory include Domain Name System (DNS) and Transmission Control Protocol/Internet Protocol (TCP/IP).

Implementation

Before implementing Active Directory in your enterprise, you will need to gather information about your organization's structure because Active Directory usually mirrors this structure in some fashion. A good way to proceed is to use a centralized planning approach with a team consisting of both technical and management representatives. You must develop a naming strategy, plan your domain structure, and consider how you will delegate administrative duties concerning Active Directory. When you delegate administrative control to Active Directory, do so at the OU level instead of at the individual object level. This makes it easier to control portions of the OU hierarchy within Active Directory. In particular, you probably want to delegate control to individuals responsible for creating users, groups, computers, and similar objects.

Consider the speed of the various links between your different geographical locations and how any systems that are not interoperable with Active Directory will be integrated into your new system. You should also profile your user community to determine what sort of domain hierarchy you will be implementing. Also consider integrating your DNS zone information into Active Directory because this will store your DNS zone information in the distributed Active Directory. Plus, it will facilitate and simplify updates of zone information through replication of domain controllers.

An important planning issue is determining where to locate domain controllers and global catalog servers for your enterprise because after Active Directory is installed and configured, the majority of Active Directory traffic is related to Active Directory clients querying Active Directory for information. Directory replication traffic is usually a less important consideration, unless the organization is in a constant state of flux. Placing a domain controller at each site will optimize queries but can increase replication traffic. Nevertheless, placing a domain controller at a site that has users in that domain is usually the best solution. If the

domain tree is large, you should not place a global catalog server at each site because this can create a lot of replication traffic. Place global catalog servers only at large regional sites. Remember that replication of modifications made to your Active Directory might take some time to propagate throughout your enterprise. For example, if you create a new user account object, it might be a few minutes before the user can actually log on to the network using the account.

Notes

The default naming convention for objects stored in Active Directory is an Active Directory canonical name of the object. This defines the object's position in a domain tree from left to right, starting with the object's name and delimited by slashes. For example, the User Account JSmith in the Marketing OU of the northwind.microsoft.com domain would have the Active Directory canonical name

```
Jsmith/users/marketing/northwind.microsoft.com
```

Active Directory supports non-DNS naming conventions for interoperability with non-DNS environments. An example is the LDAP naming convention. An LDAP Uniform Resource Locator (URL) is composed of the name of the server with the distinguished name of the object appended to it. Other naming conventions include the following:

- **User principal name:** This convention consists of the user's SAM account name with an object's user principal name suffix appended to it. The user principal name suffix is the name of the domain tree or the name of the domain above the object in the domain tree.
- **Request for Comments (RFC) number 822 name:** This naming convention is essentially the user's e-mail address.
- **Universal Naming Convention (UNC):** This convention can be used for shared resources.

Discretionary access control lists (DACLS) and system access control lists (SACLs) protect Active Directory objects. DACLS and SACLs specify which user or application has permission to access attributes of directory objects and work in a similar fashion to access

control lists (ACLs) that are implemented in the version of NTFS file system (NTFS) used in Windows NT 4. DACLs and SACLs can be used to propagate their permissions to connected directory objects. They also provide a simple way for administrators to grant access and usage rights for Active Directory to users and groups.

Active Directory Client

Client software running on a machine and enabling it to access information published in Active Directory directory service.

Overview

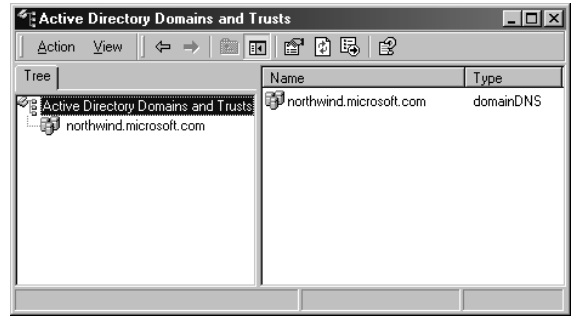

Microsoft Windows 2000, Windows XP, and Windows .NET Server come with a built-in Active Directory client so that they can participate immediately in an Active Directory-based network. Some other versions of Windows may require an Active Directory client to be installed prior to participating in such a network.

A version of Active Directory Client called the Directory Services client is available for computers running Windows 95 and Windows 98. This client allows them to log on to a Windows 2000 or Windows .NET Server domain and access information published in Active Directory. The Directory Services client can be found in the \clients folder on the Windows 2000 Server compact disc. Microsoft Internet Explorer version 5.0 or later must be installed on the machine running Windows 95 or Windows 98 prior to installing the Directory Services client. A similar client is also available for Windows NT version 4 machines.

Active Directory Domains and Trusts

A management console in Microsoft Windows 2000 and Windows .NET Server that can be used for administering domains and trust relationships.

Active Directory Domains and Trusts. The Active Directory Domains and Trusts console.

Overview

Active Directory Domains and Trusts provide administrators with a graphical representation of all the domain trees in a domain forest. Using the Active Directory Domains and Trusts, you can perform common administrative tasks such as

- Creating an explicit domain trust and managing existing trust relationships between domains
- Changing the domain mode from mixed mode to native mode
- Adding user principal name suffixes for a forest

Notes

You can also use the Active Directory Domains and Trusts to open Active Directory Users and Computers by right-clicking on a domain and then selecting Manage from the shortcut menu.

Active Directory Installation Wizard

A wizard in Microsoft Windows 2000 Server and Windows .NET Server that installs the Active Directory directory service on a machine.

Overview

Active Directory Installation Wizard promotes member servers or stand-alone servers into domain controllers. You can use Active Directory Installation Wizard to

Active Directory Installation Wizard. Using the Active Directory Installation Wizard to install Active Directory.

- Create a new domain controller with a new domain tree
- Create a new domain controller with a new child domain that is located under a parent domain in an existing domain tree
- Create a replica domain controller for an existing domain

You must be an administrator to run Active Directory Installation Wizard. Start the wizard by running the Dcpromo utility from the command prompt or choose the Run command from the Start menu, enter *dcpromo* in the Run dialog box, and then click OK. This opens the wizard's welcome screen, where you are required to make a number of decisions concerning the following:

- Whether to create a new domain or add a replica domain controller to an existing domain
- If you choose to create a new domain, whether to create a new domain tree or add a child domain to an existing tree
- If you choose to create a new domain tree, whether to create a new domain forest or add the new tree to an existing forest

Names you specify for new or existing domains, domain trees, or domain forests are based on the Domain Name System (DNS) naming system. Other steps in the wizard allow you to specify the path to the

Active Directory database, the location of the System Volume (SYSVOL) share, and so on.

Running Active Directory Installation Wizard has the following results:

- The machine on which the wizard is run becomes a domain controller. If it is the first domain controller in your domain, the wizard also creates a new site for that controller. If it is the first domain in your enterprise, it is also the root domain for any domain tree that will be created. You can use the wizard to create the first domain forest in your enterprise, too.
- The first domain controller is also your global catalog server.
- Active Directory files are located in %SystemRoot%\Ntds with the associated log files.
- The shared system volume SYSVOL, which stores scripts used for implementing group policies for your domain, is located in %SystemRoot%\Sysvol.
- A number of default organizational units (OUs) are created, namely the Users, Builtin, Computers, and Domain Controllers.

Notes

You must make sure that DNS is already installed and configured prior to running Active Directory Installation Wizard in order to create the first domain controller for your network. A DNS name will be needed for your new domain controller, and a DNS server must be available on the network during the installation process.

Active Directory files also require an NTFS file system (NTFS) volume, which must be configured as a basic volume. Dynamic volumes cannot be used for Active Directory files. Running the wizard creates a log file in the %SystemRoot%\Debug folder that shows the results of the installation procedure.

If you are creating a new child domain, an available domain controller must be in the existing parent domain. If you are creating a replica domain controller, an available domain controller must be in the target domain.

Active Directory schema

The formal term for all object classes that can be stored in Active Directory directory service and all attributes that make up these object classes.

Overview

The schema defines which kinds of objects are permitted to be published in Active Directory and states their possible attributes. The schema consists of two types of objects:

- **Classes:** These objects are predefined collections of attributes. For example, every user account on a network is represented in Active Directory by a User class object.
- **Attributes:** This is the actual information stored in an object. For example, a User class object is composed of attributes such as Name, PhoneNumber, and so on.

Attributes are defined separately from classes. This allows each attribute to be defined only once and then used in many different classes. Class definitions (such as the User class) and attribute definitions (such as the Name attribute) are themselves objects within Active Directory. This means you can manage class and attribute definitions in Active Directory with the same tools you use to manage other objects (user and group accounts, computers, and so on).

The Windows 2000 and Windows .NET Server Active Directory includes a default schema that defines commonly used object classes such as users, groups, computers, domains, organizational units (OUs), and security policies. Active Directory is extensible and can be modified using Active Directory Schema. Specifically, you can modify the schema by

- Defining new object types and their attributes
- Defining new attributes for existing object classes
- Removing attributes from existing object classes
- Removing existing object classes

Some applications such as Microsoft Exchange Server 2000 are also designed to extend the Active Directory schema for application-specific purposes.

Notes

Members of the Schema Admins group, of which the default Administrator account is automatically a member, are the only users who can make changes to the schema. A typical reason for modifying the Active Directory schema might be adding new attributes to an existing User object—for example, a SeniorityLevel attribute.

Before you can use this tool to modify the schema, you must add a registry setting to your machine and specify the one domain controller that can be used to modify the schema for your enterprise. This prevents unauthorized access to the schema and inconsistencies that can occur when the schema is simultaneously modified in more than one place.

Another way of modifying Active Directory schema is to write a script that uses Active Directory Service Interfaces (ADSI) to make calls that modify the schema. This is the best solution if you want to modify the schema for an entire enterprise or if you want to automate modifications to the schema.

Existing object classes and their attributes cannot actually be deleted; they are simply marked “defunct” in Active Directory and can no longer be used.

The schema is located under the rootDSE object, which contains information about the directory and is located at the top of the Lightweight Directory Access Protocol (LDAP) directory naming structure. You can access this object using the LDAP Uniform Resource Locator (URL):

LDAP://rootDSE

Active Directory Service Interfaces (ADSI)

A set of object-oriented programming interfaces for providing programmatic access to Active Directory objects.

Overview

Active Directory Service Interfaces (ADSI) consist of a set of general interfaces built on the Component Object Model (COM) that lets applications work with various types of directories using a single access method. ADSI works by abstracting the capabilities of directory services

from different network providers to present a single set of interfaces for managing network resources in a distributed computing network. ADSI provides a simple, open, functionally rich, and scriptable method for interfacing with any directory service, independent of the vendor.

Programmers and administrators can use ADSI to create directory-enabled applications using tools such as Microsoft Visual Basic or Microsoft Visual C++. ADSI can be used to create new users and groups, locate and manage printers, and perform other administrative functions on a Windows 2000 or Windows .NET Server network.

ADSI is only a part of a more general Microsoft family of APIs called the Windows Open Directory Services Interfaces (ODSI). Other ODSI interfaces include the Network Provider Interface, Windows Sockets Registration and Resolution (RnR), and RPC OLE DB.

Architecture

ADSI consists of two types of COM objects (directory service leaf objects and directory service container objects) that clients can manipulate with interfaces. ADSI providers are used to implement these objects and their interfaces. Each object in a given namespace is identified using a unique name. For example, file system objects can be specified using their absolute path, and directory objects are usually specified using their X.500 address. However, ADSI is flexible enough to handle any naming system used by third-party vendors' directory service implementations.

Advantages and Disadvantages

Using ADSI for directory access has the following benefits:

- **Open:** ADSI is an open platform for which any directory vendor can develop an ADSI provider.
- **Simple:** ADSI consists of a small collection of easy-to-learn programming interfaces.
- **Extensible:** Independent software vendors (ISVs) and directory service (DS) vendors can enhance ADSI by developing their own objects and functions.
- **Language independence:** ADSI is based on COM and can be used by any programming language that supports COM.

- **DS independence:** ADSI is independent of the DS being used, so developers using ADSI do not have to learn the underlying machinery of the directory they are using ADSI to access.
- **Scriptable:** Automation-compatible languages such as VBScript and Perl can be used to automate directory tasks using ADSI.
- **OLE DB aware:** ADSI can be used to access data sources through OLE DB.

Notes

Windows 2000, Windows XP, and Windows .NET Server contain ADSI providers for accessing the following types of directories:

- Active Directory directory service
- Lightweight Directory Access Protocol (LDAP)
- Novell Directory Services (NDS)
- Windows NT directory services

ADSI supports the LDAP C API defined in Request for Comments (RFC) number 1823, which specifies a low-level interface for C language programming and provides support for the Messaging Application Programming Interface (MAPI) so that legacy MAPI applications will work with Active Directory.

ADSI was formerly known as OLE DS.

Active Directory Sites and Services

A management console in Microsoft Windows 2000 and Windows .NET Server that can be used for administering sites, domain trees, domain controllers, subnets, and intersite links.

Overview

Using Active Directory Sites and Services, you can perform common administrative tasks such as

- Creating a new site and configuring replication within the site
- Configuring directory service (DS) objects and licensing site settings

Active Directory Sites and Services. The Active Directory Sites and Services console.

- Adding servers, domain controllers, intersite links, and subnets to a site
- Moving and repairing domain controllers
- Delegating control of a site

Active Directory Users and Computers

A management console in Microsoft Windows 2000 and Windows .NET Server that can be used for administering Active Directory objects and information published in the directory.

Overview

Using Active Directory Users and Computers, you can perform common administrative tasks such as

- Creating a new user, group, shared folder, computer, printer, or other resource
- Creating new organizational units (OUs) for organizing directory objects
- Moving directory objects to different OUs
- Deleting objects from the directory
- Displaying and editing the properties of directory objects
- Managing group policies and changing domain controllers

Active Directory Users and Computers. The Active Directory Users and Computers console.

- Finding objects within the Active Directory database

Notes

If you want to quickly assign permissions to network resources such as file shares, printers, users, and groups in your enterprise, simply move their associated directory objects to different servers that require the same permissions to the same OU. Objects inherit permissions from their new OU and lose permissions from their old OU. However, permissions assigned directly to an object are moved together with the object.

active hub

A hub that has electronic circuitry to regenerate weak signals.

Overview

Active hubs function as multiport repeaters, allowing computers to be networked together in a star topology. Virtually all hubs sold today are active hubs, so one generally refers to them nowadays simply as hubs.

See Also: hub, passive hub

active partition

The partition that contains the boot files for an operating system.

Overview

The active partition is the one from which the operating system boots. On a machine running Microsoft Windows 2000, Windows XP, or Windows .NET Server, the active partition must also be a primary partition and must be located on a basic disk.

Depending on the Microsoft operating system used, you can use any of the following tools to make a partition active:

- The Fdisk utility from the command prompt for MS-DOS and all Microsoft Windows platforms
- The Disk Administrator administrative tool in Windows NT
- The Computer Management administrative console in Windows 2000

Notes

Alpha-based computers running Windows NT have no active partitions. Instead, the boot volume is configured by a manufacturer-supplied configuration program.

Active Platform

A set of Microsoft technologies for developing applications for the Internet.

Overview

Active Platform is actually an umbrella term for three key Microsoft technologies:

- **Active Desktop:** Integrates the Microsoft Windows desktop with the Internet, providing a seamless connection between local and remote applications and resources. Active Desktop is a core technology of Internet Explorer.
- **Active Server:** The Active Platform component of Microsoft Internet Information Services (IIS) version 5 or later. Using Active Server technologies, core Windows NT services can be extended to the Internet using applications developed with Microsoft Active Server Pages (ASP) technologies.
- **Microsoft ActiveX:** A component software technology based on the Component Object Model

(COM). ActiveX allows distributed Web-based applications to be developed in any programming language and then run from within an ActiveX-enabled browser such as Internet Explorer.

Applications developed using Active Platform technologies can be accessed and run from any client platform independent of the operating system, as long as a standard Web browser such as Microsoft Internet Explorer is installed on the client.

See Also: *Active Desktop, Active Server Pages (ASP), ActiveX*

active scripting

Using a scripting language to drive Component Object Model (COM) components.

Overview

Host applications such as Microsoft Internet Information Services (IIS) with Microsoft Active Server Pages (ASP) and Microsoft Internet Explorer have scripting engines for running scripts written in VBScript or JScript. Active scripting engines can be developed for other interpretive scripting languages, such as Perl, to build upon a developer's existing knowledge of these programming platforms. Scripting engines for client software, such as Internet Explorer, are specially designed to eliminate the authoring components that are not needed in a nonauthoring host environment. This makes the client-side scripting engine lightweight, which yields better performance.

In a typical scenario, the host application loads the script document and calls an application programming interface (API) to create a new instance of a scripting engine. The host application feeds the script to the engine and executes the script.

See Also: *Active Server Pages (ASP)*

Active Server Pages (ASP)

An open, compile-free application environment for developing Web applications using Microsoft Internet Information Server (IIS) version 3 and later, including Internet Information Services (IIS) in Windows 2000, Windows XP, and Windows .NET Server.

Overview

Active Server Pages (ASP) can be used to build powerful, distributed Web-based applications that combine Hypertext Markup Language (HTML), script, and Microsoft ActiveX technologies to provide dynamic Web sites. ASP combines the ease of HTML with familiar programming tools such as Microsoft Visual Basic Scripting Edition (VBScript) and Microsoft JScript, along with reusable Component Object Model (COM) components. These components can be used to build powerful, dynamic Web sites. ASP executes on the Web server, and the output returned to the Web browser is a plain HTML file.

Architecture

ASP is implemented in IIS as an Internet Server Application Programming Interface (ISAPI) filter called `Asp.dll`, which resides in the same memory space as IIS. User requests for ASP pages, which have the suffix `.asp` appended to them, are processed by the filter which loads the necessary language dynamic-link libraries (DLLs) for interpreting script on the page, executes server-side script on the server, and returns the remaining HTML and client-side script to the browser requesting the page.

ASP pages have the file extension `.asp` and typically contains a mixture of HTML, scripts, and other components written in any programming language. The scripts can reference components running on either the local server or any other accessible server and can perform actions such as accessing a database, sending e-mail, or processing information in another fashion. The result is then returned by the server to the client as a standard HTML file and displayed in the usual way.

The `Asp.dll` also includes an object model that encapsulates properties and methods for seven built-in objects: `Application`, `ASPErrors`, `ObjectContext`, `Request`, `Response`, `Server`, and `Session`. These objects are available for any `.asp` page requested. For example, the `Response` object can be used to control how data is sent to the requesting client.

ASP organizes collections of ASP pages into applications, which are typically groups of files within a given virtual directory and its subdirectories. ASP applications (also known as Web applications) can have global variables and can save state information so that a session can exist across several requested pages in succes-

sion. Session-level data is initiated by reference to a file called `Global.asa`, which is checked whenever a new client makes a request to pages in an ASP application.

Examples

For example, when requested, the following ASP file will return the current time and browser type to the requesting client:

```
<HTML>
<HEAD><TITLE>Sample Web Page</TITLE></HEAD>
<BODY>
The time right now is <% = now %>
Your browser type is <%
=Request.ServerVariables("http_user_agent")
%>
</BODY>
</HTML>
```

You can use ASP to develop Web content that is customized for user preferences and demographics and that uses Microsoft ActiveX Data Objects (ADO) and open database connectivity (ODBC) to provide access to multiple data sources. ASP provides a browser-neutral approach to the design of Web applications where all of the application logic resides on the server.

Notes

Active Server Pages was first introduced as a beta technology code-named “Delani” for the Microsoft Internet Information Server 2 platform.

Unlike the stateless Hypertext Transfer Protocol (HTTP), ASP is a session-based technology. When a user connects to an ASP file on a Web server, a session object is created. After the session expires, the session object is destroyed. The default time-out for ASP applications is 20 minutes, although Outlook Web Access uses a time-out of 60 minutes.

Active Setup

A Microsoft ActiveX engine that can be used to download and install software over the Internet interactively using a Web browser.

Overview

Active Setup makes use of the fact that source files of the application to be installed are partitioned into segments, the traditional cabinet installation files (*.cab files). Active Setup begins by downloading a small, self-extracting setup package to the browser client. This file also collects information about the client's computer to help determine which components already exist on the system and whether the desired application is compatible with the system's configuration. The user specifies a location from which to download the desired application and the types of components to be installed. The application's *.cab files are then downloaded as needed, after which Active Setup is completed and normal installation can continue.

One advantage of Active Setup is that if the download is interrupted, it can be resumed at the interruption point rather than at the beginning.

active volume

The volume in Microsoft Windows 2000, Windows XP, and Windows .NET Server from which a computer boots.

Overview

In Windows 2000, Windows XP, and Windows .NET Server disk terminology, active volumes on dynamic disks are what active partitions are on basic disks. The active volume for a system must be a simple volume; in other words, it cannot be a striped set or mirrored volume.

You can upgrade the basic disk that contains the active partition to a dynamic disk, making it a simple volume that is active, but you cannot mark an existing dynamic volume as the active volume.

active window

The particular open window that has the focus on a Microsoft Windows desktop.

Overview

The active window is the window belonging to the application in which the user is currently working. If

several windows are open on a user's desktop, only one of these windows can be the active window. A unique color on the active window's title bar distinguishes it from other windows. If the user enters commands or text using the keyboard, these commands or text will be routed to the program displaying the active window. To make a window the active window on the desktop, simply click on it using the mouse, or cycle through the windows on the desktop using Alt+Tab.

Notes

You can capture a bitmap image of the active window to the clipboard by pressing Alt+PrintScreen. Then open Paint, paste the contents of the clipboard into the program, and save it as a *.bmp image.

ActiveX

An umbrella term for Microsoft technology for building lightweight reusable software components.

Overview

The term *ActiveX* was first coined at the Internet Professional Developers Conference (Internet PDC) in 1996 and was based on the conference slogan "Activate the Internet."

Microsoft ActiveX is built on the Component Object Model (COM) and Distributed Component Object Model (DCOM) technologies, which enable software components to interact with each other across a network. ActiveX does not replace object linking and embedding (OLE) but broadens and enlarges it to include the Internet and intranet technologies.

ActiveX is supported by most Microsoft development and productivity applications, including Visual Basic, Visual C++, and Office.

For More Information

Visit the Microsoft COM site at www.microsoft.com/com.

ActiveX component

A Component Object Model (COM)-based application that allows other applications to use the classes it contains.

Overview

An ActiveX component represents a server application because it can serve other applications that call it. An application that calls an ActiveX component thus functions as a client application. Other names for ActiveX components are ActiveX servers, ActiveX DLLs, and COM components.

You can create ActiveX components using tools from Microsoft Visual Studio such as Microsoft Visual Basic and Microsoft Visual C++.

See Also: *ActiveX, COM component object*

ActiveX controls

Compiled, reusable software components based on Microsoft Corporation's Component Object Model (COM).

Overview

ActiveX controls can be used as prefabricated components to help developers rapidly build user interfaces for applications. ActiveX controls can draw themselves in their own windows, respond to events such as mouse clicks, and be managed through properties and methods. An ActiveX control cannot run as a stand-alone program but must be loaded into a control container such as Microsoft Visual Basic or Microsoft Internet Explorer.

History

The earliest form of custom controls in the Microsoft Windows platform were Visual Basic Extension (VBX) controls, which were 16-bit dynamic-link libraries (DLLs) in Windows 3.1 that had specific entry points and designed to work with VB forms to provide specific graphical user interface (GUI) functionality. With the introduction of object linking and embedding (OLE), VBX controls were replaced by 32-bit OLE Custom Extension (OCX) controls that supported type libraries and had better C++ support. Unfortunately, OCX controls tended to be bloated because they contained a large number of COM interfaces, whereas the applications calling them may only require a few of these interfaces. This was a particular concern when downloading controls over the Internet, so ActiveX controls, which were basically OCX controls in which the interfaces were optional, were created. ActiveX controls are thus

lightweight controls and may even have no interface at all, as in ActiveX Data Objects (ADO).

Uses

ActiveX controls are often used to provide dynamic features for Web pages—for example, a stock ticker control that adds a live stock ticker to a Web page, an advanced user interface navigation tool, and an animation control that adds animation functionality to a page.

ActiveX controls can be embedded into a Hypertext Markup Language (HTML) page by using the HTML <OBJECT> tag. If a user tries to access such a page using a Web browser and the embedded ActiveX control is not installed on the user's system, the control can be automatically downloaded by using the URL specified in the CODEBASE attribute of the <OBJECT> tag. Once the ActiveX control is downloaded and installed on the user's system, the browser will continue to use the cached control until an updated version becomes available on the server.

Here is an example of a typical <OBJECT> tag that includes a CODEBASE attribute:

```
<OBJECT ID="BoomButton" WIDTH=225 HEIGHT=35
CLASSID="clsid:56F1BF40-B2D0-11d0-A6D6-
00AA00A70FC2"
CODEBASE="http://example.microsoft.com/
AControl.cab#Version=1,0,0,1">
</OBJECT>
```

Notes

A malicious ActiveX control can potentially damage software or data on a user's computer. To help users determine whether an ActiveX control is safe to install, Microsoft has developed a code-signing technology called Authenticode, which identifies the creator of a control using a digital signature issued by a well-known security authority such as VeriSign.

ActiveX Data Objects (ADO)

A data access interface developed by Microsoft Corporation and used for communicating with OLE DB-compliant data sources.

Overview

ActiveX Data Objects (ADO) is a high-level object-based interface to OLE DB, in other words, an OLE DB

consumer (OLE DB is a generic data access technology from Microsoft). Using ADO and OLE DB, a client application can connect to a variety of data sources using the same programming model. These data sources include relational databases, hierarchical databases, indexed sequential access method (ISAM) databases, and virtually any other kind of data source for which an open database connectivity (ODBC) driver exists. In other words, ADO is intended to be a universal information interface.

In order to communicate with these unique data sources, ADO and OLE DB employ components called OLE DB providers, which are designed for specific data sources. If a native OLE DB provider is not available for a data source, but an ODBC driver is available, it should be possible to access the data source using the ODBC driver and an OLE DB provider designed to communicate with ODBC drivers.

Uses

ADO is supported in a variety of programming environments. For example, ADO can be used in Microsoft Visual C++ and Microsoft Visual Basic to access data in an OLE DB data source such as Microsoft SQL Server. ADO can also be used in conjunction with IIS to create Microsoft Active Server Pages (ASP) applications that access data sources.

In a Web-based environment, ADO is basically a server-based solution for data access. All data operations, such as changes to database records and filtering, must take place on the server. The client can then receive the data but cannot easily manipulate it. For applications in which the client must be able to manipulate the data being accessed, use remote data binding with Remote Data Service (RDS) instead. RDS is a technology that enables the user to manipulate data on the client and have any changes automatically made on the server. Allowing data to be manipulated on the client makes Web applications faster and more responsive.

ADO 2.5 is an integral part of the Microsoft Windows 2000 platform.

Architecture

ADO is based on a collection of Component Object Model (COM) and COM+ interfaces, and its object

model is a simple COM-based architecture, which consists of static and dynamic object models. ADO communicates with a database through type libraries. Choosing the right library can significantly improve data access performance. For example, if Microsoft SQL Server is running on the same machine as Microsoft Internet Information Services (IIS), using named pipes can provide better performance than using the Transmission Control Protocol/Internet Protocol (TCP/IP) networking library.

The ADO 2.5 object model includes the following object types: Connection, Command, Errors, Fields, Record, Recordset, Parameters, and Stream.

Notes

Microsoft distributes ADO as part of the Microsoft Data Access Components (MDAC), a package that includes drivers and providers for ADO, OLE DB, and ODBC.

ADO 2.5 can also be used with ExOLEDB to provide access to the Web Storage System on Exchange 2000.

adapter

A device for connecting two different types of electronic hardware without losing information.

Overview

In local area network (LAN) networking, an adapter is a small device with two different connectors that provide data transmission back and forth between two different types of media (cabling). Adapters come in many varieties and are typically specified by stating the two connector types used and whether these connectors are male or female. For example, a DB9(f)-DB25(m) adapter means an adapter with a DB9 female and a DB25 male connector.

Adapters are a necessary part of the network administrator's toolkit because of the large number of connectivity options provided by networking equipment vendors.

Notes

The term *adapter* is also used in a number of different contexts in networking, including the following examples:

- Network interface cards (NICs) are sometimes called network adapter cards because they provide connectivity between computers and network cabling.
- Cigarette lighter adapters can be used to power cellular phones or laptops from an automobile battery.
- Digital phone adapters allow analog modems to be connected directly to Private Branch Exchange (PBX) phone outlets without damage.
- SC/ST adapters provide connectivity between fiber-optic connectors of differing types.

adaptive acceleration

An umbrella name for a group of technologies that expands the capacity of data channels.

Overview

Adaptive acceleration expands the amount of data that can be delivered over a given amount of bandwidth. This boosts network performance and helps overcome bottlenecks due to bandwidth limitations, a condition that affects most Internet service providers (ISPs), application service providers (ASPs), and other types of service providers. While throwing bandwidth at the problem is one way of handling the issue, adaptive acceleration tries to squeeze the best performance out of a fixed amount of bandwidth without dramatically increasing costs.

Adaptive acceleration works by combining several different techniques. These techniques can be incorporated into switching or routing gear or into stand-alone appliances and are targeted particularly towards traffic carried over the Internet. Some of the techniques used in adaptive acceleration include

- **Adaptive packet compression:** This assigns a different data compression algorithm to different types of data. For example, Hypertext Markup Language (HTML) files compress differently from Microsoft Word files, and adaptive packet compression scans packets for different kinds of files and compresses them in the most efficient manner for each type.
- **Selective caching:** This technique makes use of advanced algorithms to determine which files (or

portions of files) can benefit most by being cached. For example, an entire Word file might be cached, or only the properties of the file. As another example, a .gif image might be cached, or only its palette.

- **Vertical data analysis:** This technique uses an algorithm that parses the different level protocol headers in packets, compresses it, repackages it, and applies rules to handle it more efficiently. This makes data transfer more efficient and can enhance and prioritize time-sensitive traffic such as voice or video over IP.

Adaptive Differential Pulse-Code Modulation (ADPCM)

A technique for converting analog sound, such as speech, into binary digital information by frequently sampling the sound and expressing its modulation in binary form.

Overview

Adaptive Differential Pulse-Code Modulation (ADPCM) codecs convert analog signals into digital information by quantizing the differences between the actual analog signal and a predicted signal. The result is that analog signals encoded into files using ADPCM have a smaller size than many other formats. ADPCM enables speech information to be compressed into small files for storage and transmission.

Personal Communications Services (PCS) cellular telephony systems use a 32-kilobits per second (Kbps) ADPCM coding system to provide the same quality of voice communication that is available in wired telephone networks. This standard was developed by the International Telecommunication Union (ITU) and is known as G.721.

ADC

Stands for analog-to-digital converter, any device for changing analog signals into digital transmission.

See: analog-to-digital converter (ADC)

address book view

A virtual container in Microsoft Exchange that lets Microsoft Exchange Server administrators group recipients according to common attributes.

Overview

Address book views are created automatically when you establish the defining attributes for the address book view. For example, using the Exchange Administrator program, you could create an address book view called By Department and use the Department attribute of the recipients in your Exchange organization to automatically generate various address book view containers called Sales, Marketing, Management, and so on. Each address book view container will contain only those recipients that belong to a specific department.

For instance, when users access the global address list using Microsoft Outlook, these containers will be visible in their address books, along with their recipients. This allows users to more quickly address e-mail to recipients in a particular department instead of scrolling down the entire global address list.

You can also create multilevel address book views. For example, you could create a first level of virtual containers sorted by Country, followed by a second level sorted by State.

Notes

If you use the Exchange Administrator program to move a recipient from one address book view to another, the recipient takes on the defining attributes of the new address book view.

address record

A Domain Name System (DNS) record mapping a host name to an Internet Protocol (IP) address.

See: A record

Address Resolution Protocol (ARP)

The Transmission Control Protocol/Internet Protocol (TCP/IP) network layer protocol responsible for resolv-

ing Internet Protocol (IP) addresses into Media Access Control (MAC) addresses.

Overview

When a TCP/IP-aware application tries to access another TCP/IP host using its IP address, the destination host's IP address must first be resolved into a MAC address so that the frame can be addressed and placed on the wire and then be recognized by the destination host's network interface card (NIC). This is because NICs operate at the physical layer (Layer 1) and data-link layer (Layer 2) of the Open Systems Interconnection (OSI) reference model and must use physical addresses (such as MAC addresses) instead of logical addresses (such as IP addresses) for network communication.

Address Resolution Protocol (ARP). How ARP works.

Address Resolution Protocol (ARP) broadcasts an ARP request packet that effectively says, "Who has the following IP address?" This broadcast requests the MAC address of the destination host. The destination host then responds with an ARP reply packet containing its own MAC address. The requesting host next temporarily stores the IP-to-MAC-address mapping in its local ARP cache in case this is required again within a short time.

Notes

If the destination host is on a remote network, ARP obtains the MAC address of the local router interface that connects the local network to the remote network.

ARP is defined in RFC 826.

ADMD

Stands for Administrative Management Domain; in X.400 messaging, a message-handling system (MHS) that is managed by a registered private agency.

See: *Administrative Management Domain (ADMD)*

ADMIN\$

A special administrative share created during installation on computers running Microsoft Windows 2000, Windows XP, and Windows .NET Server and used for remote administration of the computer.

Overview

The Administrators group is assigned full control permissions on the ADMIN\$ share on a Windows 2000, Windows XP, or Windows .NET Server system. This allows administrators to access the share and remotely administer the system without needing to know where the system files are stored. Only the Administrators group has access to the ADMIN\$ share.

This share's path is always the path to the %SystemRoot% directory (usually C:\Winnt).

administrative alert

A pop-up dialog box in Microsoft Windows 2000, Windows XP, and Windows .NET Server that notifies users of problems or issues.

Overview

Administrative alerts are generated by the Alerter service in Windows 2000, Windows XP, and Windows .NET Server. These alerts can be directed towards specified users and computers.

Administrative alerts are typically displayed when problems with security, access, sessions, directory replication, or printing occur or when a server is shut down by an uninterruptible power supply (UPS) device.

See Also: *service*

Administrative Management Domain (ADMD)

In X.400 messaging, a message-handling system (MHS) that is managed by a registered private agency.

Overview

Administrative Management Domains (ADMDs) are usually large public telecommunications carriers such as MCI/WorldCom and AT&T. This is in contrast to a Private Management Domain (PRMD), which represents a message-handling system managed by a private corporation. In the X.400 world, PRMDs cannot communicate directly with each other; instead, they must communicate through ADMDs. All the ADMDs in the world therefore form a kind of messaging backbone for global X.400 communication.

Notes

The ADMD is the second field in a typical X.400 originator/recipient (O/R) address and is located right after the country field.

administrative share

A share created during setup by Microsoft Windows 2000, Windows XP, and Windows .NET Server for system purposes and remote administration.

Overview

Administrative shares end in the "\$" character, which makes them hidden shares. You cannot modify the permissions on these shares and you cannot remove the shares.

Some examples of administrative shares include

- **C\$, D\$, and so on:** The shares used by administrators to connect to the root of each volume on a

network server and perform remote administration such as creating and deleting files and folders

- **ADMIN\$:** The share name for the %System-Root% folder, used by the system during remote administration
- **IPC\$:** A share used by interprocess communication (IPC) resources for sharing the named pipe interface, which allows applications running on different computers to communicate over the network
- **PRINT\$:** A share used to support shared printers
- **REPL\$:** A share used by the Directory Replicator Service that allows directory trees to be exported
- **NETLOGON:** A share used by the NetLogon service that enables the processing of domain requests

administrative tools (Windows 2000, Windows XP, and Windows .NET Server)

A program group in Microsoft Windows 2000, Windows XP, and Windows .NET Server containing tools for administering a network based on these versions of Windows.

Overview

Most Windows 2000 administration tools are primarily implemented as preconfigured snap-ins for the Microsoft Management Console (MMC). Such tools are commonly referred to as consoles. Each administrative tool corresponds to an MMC console with a particular snap-in installed.

The set of available tools for a particular machine running Windows 2000, Windows XP, or Windows .NET Server depends on how that machine was installed and configured. Commonly installed tools for Windows 2000 Server, Windows XP, and Windows .NET Server, which can be used for both local and remote administration, include

- Component Services
- Computer Management
- Configure Your Server

- Data Sources (ODBC)
- Distributed File System
- Event Viewer
- Internet Services Manager
- Licensing
- Local Security Policy
- Performance
- Routing and Remote Access
- Server Extensions Administrator
- Services
- Telnet Server Administration

Notes

As an administrator, you can create your own administrative tools by opening a blank MMC console and installing the various snap-ins you need. When you save this tool, it will automatically be saved in the Administrative Tools program group.

administrative tools (Windows NT)

A program group in Microsoft Windows NT containing tools for administering a Windows NT-based network.

Overview

The basic set of tools for Windows NT Server 4 consists of the following:

- Administrative Wizards
- Backup
- Disk Administrator
- Event Viewer
- License Manager
- Migration Tool for NetWare
- Network Client Administrator
- Performance Monitor
- Routing and Remote Access Admin

- Server Manager
- System Policy Editor
- User Manager for Domains
- Windows NT Diagnostics

You can extend these basic tools by installing additional Windows NT services using the Network utility in Control Panel, which provide the following additional tools:

- DHCP Manager
- DNS Manager
- File Manager
- Network Monitor
- WINS Manager

Notes

You can install a subset of these administrative tools on Windows NT Workstation 4 and a smaller subset on Windows 95 or Windows 98. The files required to install the client-based network administrative tools on Windows NT Workstation 4 and Windows 95 or Windows 98 are available in the \Clients\Srvtools directory on the Windows NT Server 4 compact disc.

administrator

A user who has full rights and permissions to manage any resources on the network.

Overview

The administrator is usually responsible for tasks such as installing, managing, and controlling servers and networking components. Administrators can also modify the properties of user accounts and the membership of groups, create and manage security printers, install printers, share resources, and assign permissions to those resources.

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, the Administrator account is a built-in account whose password is defined during installation. The Administrator account is a member of

the Domain Admins group and the Administrators group on the domain controller on which it is defined, and it has full rights and permissions on all user-accessible system resources.

Notes

On a domain controller, the Administrator account is a global user account, while on a stand-alone server or workstation, the Administrator account is a local user account.

You can rename the default Administrator account, but you cannot delete it. If you rename the account, make sure you remember what the new name is!

See Also: Administrators group

Administrators group

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a built-in group whose default membership consists of the Domain Admins group.

Overview

The Administrators group has full rights on all user-accessible processes on a computer running Windows 2000, Windows XP, or Windows .NET Server. For example, on a domain controller, the Administrators group has the right to

- Log on locally
- Access the computer over the network
- Take ownership of files
- Change the system time
- Configure auditing and manage the security log
- Shut down the system
- Back up and restore files and directories
- Force shutdown from a remote system
- Load new device drivers
- Add computers to the domain in Windows NT and Windows 2000

ADO

Stands for ActiveX Data Objects, a data access interface used to communicate with OLE DB–compliant data sources.

See: ActiveX Data Objects (ADO)

ADO+

A version of Microsoft ActiveX Data Objects (ADO) for the Microsoft Windows Distributed interNet Applications Architecture (Windows DNA).

Overview

ADO+ is a more scalable, more interoperable, and more strongly typed version of ADO. The programming and object model for ADO+ is radically different from ADO because ADO is designed from the ground up to work with disconnected data sets (ADO included some support for disconnected record sets starting with ADO 2.0). An ADO+ data set is a disconnected in-memory view of a database. Data sets can be created dynamically without any interaction with a database management system (DBMS), so data sets are an evolution of the previous concept of ADO record sets. Data sets can contain any number of tables, and these do not need to correspond to a particular database table or view. ADO+ thus models data, not databases or data providers the way ADO did.

What particularly distinguishes ADO+ is that it utilizes Extensible Markup Language (XML) as its universal format for data transmission. This gives ADO+ its wide interoperability with any platform supporting XML, and receivers no longer need to be COM objects as they were with ADO.

ADO.NET

The evolution of Microsoft Corporation's Active X Data Objects (ADO) for its new .NET platform.

Overview

ADO.NET provides the classes necessary to ADO to enable access to Extensible Markup Language (XML)

documents and relational data stores. Some of the differences between ADO.NET and ADO are the following:

- While ADO uses the RecordSet object, which looks like a single table, ADO.NET uses the DataSet object, which can contain one or more tables represented by DataTable objects.
- While ADO uses Component Object Model (COM) marshalling to transmit a disconnected record set, ADO.NET transmits a DataSet with an XML file (the XML format places no restrictions on data types and requires no type conversion).
- While ADO has trouble transmitting data through firewalls because firewalls are typically configured to prevent system-level requests such as COM marshalling, ADO.NET can easily transmit data through firewalls because ADO.NET DataSet objects use Hypertext Markup Language (HTML)–based XML, which can pass through firewalls.

ADR

Stands for Advanced Data Recording, a tape backup technology developed by Philips.

See: Advanced Data Recording (ADR)

ADSI

Stands for Active Directory Service Interfaces, a set of object-oriented programming interfaces for providing programmatic access to Active Directory objects.

See: Active Directory Service Interfaces (ADSI)

ADSL

Stands for Asymmetric Digital Subscriber Line, a form of Digital Subscriber Line (DSL) technology that provides subscribers with high-speed voice and data services over twisted-pair copper phone lines.

See: Asymmetric Digital Subscriber Line (ADSL)

ADSL modem

A modem used to terminate an Asymmetric Digital Subscriber Line (ADSL) connection between the customer premises and the ADSL provider.

Overview

ADSL modems are customer premises equipment (CPE) for connecting subscribers to telcos offering ADSL services. ADSL modems are typically used to provide high-speed Internet access for residential and business customers.

ADSL modems operate by dividing the available bandwidth in Plain Old Telephone Service (POTS) telephone lines into separate upstream and downstream channels. This is typically done in one of two ways:

- **Frequency division multiplexing (FDM):** This technique separates upstream and downstream communications into two separate channels with a band of unused frequency between them to prevent crosstalk and reduce interference. If you need to, you can then further divide each of these two channels using time-division multiplexing (TDM).
- **Echo cancellation:** This technique employs overlapping upstream and downstream channels and separates them using V.32/V.34 echo cancellation methods used in modems.

Of these two techniques, echo cancellation offers better utilization of bandwidth but is more complex to implement.

To separate the two data channels from the voice channel used for ordinary telephone communications, ADSL modems include a POTS splitter, a type of filter placed at the carrier side of the modem which splits off the first 4 kilohertz (kHz) of bandwidth and routes it to the telephone. This way, if an ADSL provider goes down and data communications cease, regular POTS telephone service still works at the customer premises.

Advanced Configuration and Power Interface (ACPI)

A specification for power management of computer hardware.

Overview

Advanced Configuration and Power Interface (ACPI) is an open industry specification that was designed to enable software designers to integrate power management features through all parts of a computer system, including the hardware, the operating system, and application software. ACPI is the successor to the Advanced Power Management (APM) specification and differs by allowing the operating system to control hardware power consumption instead of the basic input/output system (BIOS).

Microsoft Windows 2000, Windows XP, and Windows .NET Server support Advanced Configuration and Power Interface (ACPI), and it enables Windows to handle all the power-management resources for computer subsystems and peripherals. ACPI works with subsystems and peripherals for a wide range of mobile, desktop, and server platforms. ACPI is also the foundation for the OnNow industry initiative that enables computers to start at the touch of the keyboard.

Notes

Your PC must be fully compatible with ACPI for you to use it, regardless of whether your operating system supports it. To find out if your PC supports ACPI, go into the BIOS, look for an ACPI option, and turn it on.

You can also enable ACPI support for Windows 98 by running Setup using the command-line switch Setup /p j. Running Setup in this mode adds the ACPIOption

string value with a value data of 1 to the Windows 98 registry and causes hardware devices to be queried for ACPI support during setup. Note that Windows 98 does not support all ACPI features—Passive Cooling Mode, for example.

Advanced Data Recording (ADR)

A tape backup technology developed by Philips.

Overview

Advanced Data Recording (ADR) is a technology that writes eight tracks of data simultaneously to a single tape. This gives ADR tape drives a very high throughput. Tapes move slowly in ADR tape drives, which makes for minimal tape wear and quieter operation.

ADR tape drives are available from OnStream and popular models include:

- **ADR30:** Has a capacity of 15 gigabytes (GB) and a transfer rate of 60 megabytes (MB)/min.
- **ADR50:** Has a capacity of 25 GB and a transfer rate of 120 MB per minute.

Advanced Encryption Standard (AES)

The new U.S. government encryption standard adopted to replace the aging Data Encryption Standard (DES) standard, which no longer offers sufficient security.

Overview

Until recently the U.S. government has used DES as the encryption scheme for security sensitive electronic transmissions. However, a 56-bit DES key was success-

fully cracked in 1997 using idle processing cycles on thousands of machines distributed across the Internet. Advances in computing in the last few years have made DES even more vulnerable as an encryption mechanism, and as a result an initiative was put forward by the U.S. government to develop a scheme that could not be cracked.

The result of this initiative is the Advanced Encryption Standard (AES), which officially replaced DES in the spring of 2001. AES supports key lengths of 128, 192, and 256 bits, which offers a vast improvement in security over 56-bit DES and even 168-bit Triple DES, in which three DES keys are applied in succession. The National Institute of Standards and Technology (NIST) has calculated that it would take about 149 trillion years to crack an AES-coded message using an algorithm that could crack DES in one second (no such algorithm currently exists), so AES is likely to remain secure for some time to come. Using the maximum level of encryption (256-bit), a cracker would have to generate and test 1.1×10^{77} unique keys in order to crack an AES message, which is currently beyond conception for brute-force computing power.

Architecture

AES is a block cipher, which means that it encrypts data in fixed-length blocks of 128 bits at a time. AES uses the Rijndael algorithm developed by Vincent Rijmen and Joan Daemen. This algorithm was chosen over four competing algorithms because it is easy to implement and is efficient with regard to calculation, making AES suitable for use even in devices such as cell phones and Personal Digital Assistants (PDAs) that have limited processing power. The Rijndael algorithm executes 10 rounds of encryption when using a key length of 128 bits.

Prospects

Although AES has become the official standard for U.S. government encryption, it will continue to coexist with DES and Triple DES for a number of years as hardware and software vendors update their encryption schemes. However, industry is expected to quickly upgrade to AES because DES is no longer secure and Triple DES is inherently slow. AES will also be licensed for commercial use by industry.

Notes

Web browsers, the ubiquitous interface to Web applications, mostly use RC4 encryption. Although the next generation of Web browsers will likely license AES for use, millions of desktop computers are likely to continue to use older browsers for years.

Advanced Infrared (AIr)

A wireless networking technology for high-speed, low-cost infrared (IR) networking.

Overview

Advanced Infrared (AIr) allows ad hoc multipoint wireless peer-to-peer connections to be formed simultaneously between multiple wireless information appliances such as Personal Digital Assistants (PDAs), cellular phones, laptops, and digital cameras. The devices must be within 26 feet (8 meters) of each other to reliably communicate without interference.

AIr ports can receive signals within a 120-degree cone, which means that the ports need not be precisely aimed at each other to achieve reliable transmission.

AIr currently supports data throughput of up to 4 megabits per second (Mbps) for direct line-of-sight communication, but it can interoperate with the existing slower Infrared Data Association (IrDA) 1.1 standard, and it supports the Very Fast Infrared (VFIR) standard currently under development.

IBM developed AIr and was the first vendor to release products based on this standard. IBM is working with the IrDA to standardize the technology.

Advanced Intelligent Tape (AIT)

A tape backup technology developed by Sony Corporation.

Overview

Advanced Intelligent Tape (AIT) is a popular tape backup format that has a native capacity of 25 gigabytes (GB) (uncompressed) per tape and supports transfer speeds of 6 megabits per second (Mbps). AIT supports high data compression rates—typically 2:1 or higher. Access times are low because the tape's spine contains embedded 16-kilobyte (KB) nonvolatile memory chips that store the backup set headers. Thus, when a particular backup set is requested, the tape can spool directly to the required spot without having to search through the data. This results in longer life for the tape. Another feature of AIT is that the heads are self-cleaning and only occasionally require maintenance, which also extends media life.

Sony's AIT tape drives are typically cheaper than Quantum's digital linear tape (DLT) drives, and they have gained a solid foothold in large companies. AIT tape libraries are also available from various vendors for terabyte storage needs.

AIT 2 is a second-generation AIT standard and supports up to 50 GB (uncompressed) per tape, but this can often translate into up to 125 GB compressed. AIT 2 transfer speeds are typically 7 megabytes per second (MBps) or higher. AIT 3 is emerging as the next generation of AIT standards, and it should be competitive with the 100 GB native capacity and 13 MBps transfer rates of the competing Linear Tape Open (LTO) tape backup technology.

Advanced Mobile Phone Service (AMPS)

The original first-generation (1G) analog cellular phone service. Still used in some parts of North and South America.

Overview

Bell Laboratories invented the technology for Advanced Mobile Phone Service (AMPS) in the 1970s, and AT&T introduced it as a commercial service in

1983. AMPS represents the first generation of cellular phone technology widely deployed throughout the United States and was the first fully standardized automatic mobile telephone service in the world. In addition to the United States, AMPS was also deployed in South America, Australia, and China.

AMPS uses frequencies in the 800 megahertz (MHz) band (from 824.04 to 893.7 MHz) of the radio spectrum. AMPS uses Frequency Division Multiple Access (FDMA) to create individual communications channels. FDMA is used to modulate a 3 kilohertz (kHz) voice channel onto a 30 kHz carrier signal using frequency modulation (FM). This creates a series of 30 kHz wide channels for one-way transmission (by contrast, an FM radio station uses a 150 kHz bandwidth channel). Separate channels are used for base station to mobile transmission (forward channels) and mobile station to base transmission (backward channels). In fact, forward channels fall within the range 869.04 to 893.97 MHz and backward channels are found from 824.04 to 848.97 MHz. The 45 MHz between these two bands helps separate forward and reverse transmission and reduces interference and crosstalk.

AMPS can assign only a single subscriber at a time to each channel, so the resulting allocation of bandwidth results in a maximum of 832 simultaneous phone conversations per operator. Because the population of most cities would suggest that 800 simultaneous phone conversations is far from enough, the idea was developed to partition the coverage of cities into a number of small areas called “cells” (this explains the origin of the terms “cellular communications” and “cell phone”). Each base station uses a limited-power transmitter with a directional antenna to provide coverage for a small geographical cell. A typical cell ranges from 1640 feet (500 meters) to 12.5 miles (20 kilometers) in size, depending on whether the coverage is in a densely populated urban area or a sparsely populated rural one.

Because cell phones have limited transmission power, communication is limited to the base station servicing the immediate cell the user is currently in. As a user moves from one cell to another, the signal strength

gradually decreases until a threshold limit is reached. Once this threshold is reached, the base station informs the Mobile Telephone Switching Office (MTSO) that the subscriber is leaving the service area of that base station. The MTSO hands off the call to the base station that the subscriber is starting to enter (adjacent cells overlap), which smoothly picks up the call so service is not interrupted. Adjacent cells employ different frequencies to help prevent interference from occurring between them.

Handheld AMPS cellular phones have power levels generally under 0.6 watts with a range of about 5 miles (8 kilometers) from the base station, but power levels in vehicle-mounted phones reach up to 3 watts with a range of 15 miles (24 kilometers). Base stations themselves generally have power levels up to about 1 kilowatt.

Prospects

Because of the need for data transmission and security (encryption), digital cellular phone services such as Time Division Multiple Access (TDMA) and Code Division Multiple Access (CDMA) systems are steadily increasing in popularity as AMPS continues to decline. Nevertheless, market statistics indicate that as recently as 1999 AMPS remained the cellular communications service with the greatest area of coverage across North America. However, the success of AMPS has been its downfall—the limited number of channels per cell means that when too many people subscribe to the service, blocking (the inability to make a call because no channel is available) becomes a problem. Another problem is that when a subscriber roams into a cell where no channels are available, the subscriber’s call is dropped (suddenly disconnected without warning).

Notes

Other 1G analog cellular phone systems included Total Access Communication System (TACS) and Extended TACS (E-TACS) used in the United Kingdom and Nordic Mobile Telephone (NMT) used in the Scandinavian countries. AMPS, however, was by far the most popular and widely deployed 1G service.

AMPS can also be used for data transmission, but it is capable of supporting data rates of only about 9.6 kilobits per second (Kbps).

Advanced Peer-to-Peer Networking (APPN)

A protocol developed by IBM as the second generation of Systems Network Architecture (SNA).

Overview

Advanced Peer-to-Peer Networking (APPN) is an extension of SNA that was developed for several reasons:

- To enable SNA traffic to flow concurrently with other protocols.
- To provide for prioritization of SNA traffic through it is class-of-service (CoS) features.
- To allow users to establish communication sessions without mainframe involvement.

APPN provides a mechanism for peer-to-peer networking and session establishment between any two logical units (LUs) on an SNA network. APPN provides greater distributed network control than legacy SNA by isolating the effects of single-point failures. It supports the dynamic exchange of information about network topology to facilitate connection, reconfiguration, and route selection. APPN also supports the dynamic definition and automated registration of network resources.

Prospects

APPN was a promising technology that for various reasons ended up failing to make much of an impact on mainframe computing environments. APPN equipment

was costly and difficult to manage, and IBM's marketing scheme of requiring third-party developers of APPN hardware and software to contribute royalties from earnings to IBM led to a famous clash between IBM and Cisco Systems in 1994 over this issue. APPN is today considered a legacy technology that is being phased out.

Advanced Power Management (APM)

A legacy specification for power management of computer hardware.

Overview

Advanced Power Management (APM) was the precursor to Advanced Configuration and Power Management (ACPI) and was implemented in versions of Microsoft Windows prior to Windows 2000. APM used the basic input/output system (BIOS) to manage all computer hardware and peripherals. This had several disadvantages that motivated the development of ACPI, namely

- Different hardware platforms from different vendors often used different BIOS chips, which meant that in a large enterprise power management capabilities varied from machine to machine, making troubleshooting more difficult.
- Suspend mode is supported poorly because the BIOS cannot know whether the user or the system initiated the suspend.
- Universal serial bus (USB) and Institute of Electrical and Electronics Engineers (IEEE) 1394 peripherals were not supported by APM.

ACPI addresses these concerns by enabling the operating system to control power to devices, not the BIOS.

Notes

If your machine's BIOS uses APM 1 or 1.1, try to flash upgrade the BIOS to support APM 1.2 if possible to resolve certain issues relating to system instabilities when in standby mode.

Microsoft Windows 2000, Windows XP, and Windows .NET Server support both APM and ACPI, with ACPI being the preferred option. The tool Ampstat.exe in the Support/Tools folder on the Windows 2000 CD can be used to troubleshoot issues relating to APM.

Advanced Program-to-Program Communications (APPC) protocol

A set of protocols developed by IBM that enables transactional programs to communicate with each other.

Overview

The Advanced Program-to-Program Communications (APPC) protocol was originally designed for Systems Network Architecture (SNA) networks and has been implemented in Multiple Virtual Storage (MVS), Operating System/2 (OS/2), Advanced Interactive Executive (AIX), and OS/400. APPC is also supported over Transmission Control Protocol/Internet Protocol (TCP/IP) using IBM's Anynet architecture. APPC was first introduced into the AS/400 series as its native communications platform and was called LU 6.2.

Applications that use APPC to communicate are called transaction programs (TPs) and utilize a package of APPC routines called Common Programming Interface-Communications (CPIC). APPC services are available for applications written in C++, REXX, COBOL, and other languages.

APPC is not a widely deployed platform and is most often employed for its file transfer services.

Notes

Microsoft Host Integration Server provides services necessary for APPC connectivity with AS/400 systems and mainframe hosts.

Advanced Streaming Format (ASF)

A method of streaming data supported by Windows Media Player.

Overview

Advanced Streaming Format (ASF) supports video, audio, images, Uniform Resource Locators (URLs), and scripts. ASF streams can combine different types of data, allowing you to stream presentations involving slides and audio narration. Using the Windows Media Encoder, you can generate live ASF streams that contain audio and video.

You can also use tools provided with Windows Media Encoder to create and store ASF files that you can later stream.

Windows Media Services can deliver ASF streams using either multicasting or unicasting.

Notes

When multicasting an ASF stream, configure Windows Media Services to provide a supplemental unicast source for the stream for any clients that cannot receive multicasts.

Advanced Technology Demonstration Network (ATDnet)

A high-speed test bed network that is part of SuperNet, the cross-country network funded by the Next Generation Internet (NGI) program.

Overview

Advanced Technology Demonstration Network (ATDnet) is deployed in the Washington D.C. area and was developed as a prototype for the next generation of Metropolitan Area Networks (MANs). It is funded by the Defense Advanced Research Projects Agency (DARPA) and serves as an experimental test bed platform for research and development. ATDnet network transport consists of Synchronous Optical Network (SONET) and Asynchronous Transfer Mode (ATM)

running over fiber and currently uses a double ring topology that supports 20 gigabits per second (Gbps).

For More Information

You can visit ATDnet at www.atd.net.

AES

Stands for Advanced Encryption Standard, the new U.S. government encryption standard adopted in the spring of 2001 to replace the aging Data Encryption Standard (DES) standard, which no longer offers sufficient security.

agent

Simple Network Management Protocol (SNMP) client software that runs on a hub, a router, or another networking component.

Overview

Agents collect information about Transmission Control Protocol/Internet Protocol (TCP/IP) statistics and conditions and can supply this information when requested to an SNMP management system. Agents can also alert management systems to errors and other conditions when a trap occurs. SNMP agents are identified by the community to which they belong. By default, SNMP agents listen to TCP port number 161 for SNMP messages and to port number 162 for SNMP traps.

An agent must be installed on each networking component or host that will be managed in an SNMP-managed network. The agent program can then perform operations such as

- Get operations initiated by the SNMP management console for obtaining information about a specific managed object in the host Management Information Base (MIB)

- Get-next operations initiated by the management console to continue traversing the MIB database from the point at which it was accessed by a get operation
- Set operations initiated by the management console to set a value for a managed object (if permissions allow this)
- Trap operations initiated by the managed host itself when an error condition occurs, such as when the computer's disk becomes full

Notes

Windows 98 also includes an SNMP agent conforming to SNMP 1 specifications that lets you monitor remote connections to machines running Windows 98 from an SNMP management console. This agent is implemented as a Win32 service using Windows Sockets over TCP/IP. You can install the Microsoft SNMP agent on Windows 98 using the Network utility in Control Panel.

AGLP

A mnemonic for managing an enterprise-level Microsoft Windows NT network.

Overview

AGLP means that user **A**ccounts are organized by placing them in **G**lobal groups, which are then placed into **L**ocal groups that have appropriate **P**ermissions and rights assigned to them.

In practice, the steps for administering a Windows NT enterprise-level network are the following:

- 1 Create global user accounts for users in the account domains or master domains.
- 2 Create global groups in these domains to organize users according to function, location, or some other criteria (or use the Windows NT built-in groups if these suffice).
- 3 Assign global users to their respective global groups.
- 4 Determine who needs access to network resources in the resource domains.

- 5 Create local groups on domain controllers and member servers within the resource domains (or use the Windows NT built-in groups if these suffice).
- 6 Assign rights and permissions to each local group as desired to provide access to network resources.
- 7 Place global groups into local groups as desired to provide users with permissions to access resources.

AGLP. Using AGLP to administering a Windows NT-based network.

Notes

On Windows 2000– and Windows .NET Server–based networks, the mnemonic is AGDLP because local (L) groups are referred to as domain local (DL) groups. However, because Windows 2000 and Windows .NET Server include an additional type of group (universal groups) and have a more flexible architecture for deployment, these mnemonics do not have as much significance for these versions of Windows as they did for Windows NT.

Air Interface

Generally, the lower levels of the protocol stack in a wireless communications system.

Overview

Different wireless communications systems use different types of air interfaces, but these all generally map well with the Open Systems Interconnection (OSI) model for networking. For example, Personal Communications Service (PCS) cellular service uses a three-level air interface:

- **Physical Layer:** This bottom layer of the interface is responsible for encoding and framing data, interleaving and slotting it into available time slots, and mapping these slots onto a channel for transmission as a burst.
- **Data-link Layer:** This middle layer is responsible for packaging the data, transporting the message to its destination, and performing error correction.
- **Message Layer:** This top layer handles messages transmitted over the air and formats the messages as data elements that are then packaged and transported by the lower levels.

In addition to these three levels, typical wireless messaging systems include higher levels for control purposes, metering, and providing additional services.

AIX

A version of the UNIX operating system developed by IBM.

Overview

AIX runs on IBM RS/6000 and systems based on IBM PowerPC processors (a version for Intel Corporation's 64-bit IA-64 processor is also planned). AIX, which stands for Advanced Interactive Executive, was originally based on release 2 of the Unix System V operating system and is compliant with the Unix98 standard. The current release AIX 4.3 is a solid platform for e-business and supports IBM's VisualAge, Java, and C++ developer tools.

Project Monterey is an initiative from IBM for the development of the next version of AIX called AIX 5L. Combining the time-tested reliability of AIX with UnixWare, DYNIX/ptx, and Linux support, AIX 5L promises to make AIX a major contender for high-end 64-bit computing using Intel's 64-bit IA-64 platform.

Alerter service

A Microsoft Windows 2000, Windows XP, and Windows .NET Server service responsible for sending administrative alerts to users and computers.

Overview

The Alerter service generates an alert when potentially dangerous conditions occur, such as when disk space is running out. You can configure which users or computers receive these alerts by using Server Manager (or by using the Server utility in Control Panel). Pop-up alert messages appear if the administrator is logged on or is at the appropriate computer when the alert occurs. The administrator can then consult the system log for information about what caused the alert.

Notes

The Server service must be running for the Alerter service to function. The Messenger service should also be running on both the sending and receiving computers. Also, restart the Server service and Alerter service on the computer after modifying the list of users and computers to whom alert conditions on that computer should be sent.

alias

A form of nickname that identifies a user for e-mail purposes.

Overview

An alias is usually a shortened form of the user's full name, such as the alias JSmith or JeffS for user Jeff Smith.

Aliases are a convenient way of identifying users and form the user-specific portion of an e-mail address. For example, if Jeff Smith belongs to a company whose Domain Name System (DNS) domain on the Internet is northwind.microsoft.com, his e-mail address would be either JSmith@northwind.microsoft.com or, instead, JeffS@northwind.microsoft.com, depending on which alias is selected.

Notes

What if both a Jeff Smith and a Jeff Smythe work at the same company? If JeffS is the alias for the first user, you could use JeffS2 for the second. It all depends on your choice of naming convention.

Always On/Dynamic ISDN (AO/DI)

A modified form of Integrated Services Digital Network (ISDN) that supports transmission of data over the ISDN control channel (D channel).

Overview

The ISDN D-channel is always active and is normally used to carry the control information for setting up, managing, and tearing down ISDN B channel connections. Always On/Dynamic ISDN (AO/DI) takes advantage of this by reserving a portion of the D channel's bandwidth for transmitting X.25 packets. This is done by encapsulating X.25 packets within Point-to-Point Protocol (PPP) and allows an X.25 Packet Assembler/Disassembler (PAD) at the subscriber's premises to transmit and receive information through ISDN to the carrier's X.25 network.

The ISDN D channel has a total bandwidth of 16 kilobits per second (Kbps). This is more than enough for carrying ISDN control signals, so in AO/DI 9.6 kbps of this bandwidth is used for X.25 signaling. When an X.25 packet is sent from the customer premises over an ISDN D channel to the telco's central office (CO), a packet handler positioned in front of the carrier's ISDN switch strips off the X.25 packet and relays it to the carrier's X.25 network.

Uses

Although 9.6 Kbps seems like a small amount of useful bandwidth, one use for AO/DI is to provide always-on Internet access to subscribers who can utilize this small bandwidth for practical purposes, such as periodically polling fire alarm sensors over the Internet from a central monitoring station or remotely monitoring electricity and gas meters. From the telco's point of view, the main advantage of AO/DI is to reduce the usage of ISDN B channels, freeing up more circuits and saving costs.

Despite its promised usefulness, real-world deployments of AO/DI are few, primarily due to the communications industry's current focus on developing high-speed broadband access solutions for home and business.

Alpha platform

A computer hardware platform whose processor is based on the Alpha Reduced Instruction Set Computing (RISC) microprocessor architecture originally developed by Digital Equipment Corporation (DEC).

Overview

Alpha-based systems, which are used primarily for high-performance servers and workstations, can run operating systems such as Microsoft Windows NT, Digital UNIX, and OpenVMS. For example, the Alpha 21164 processor was specifically designed for running Windows NT desktop applications and includes a new set of motion video instructions (MVI) for high-performance multimedia applications. The superscalar design of this processor integrates a 16-kilobyte (KB) instruction cache, an 8-KB data cache, and a 96-KB second-level cache and can issue four instructions for each clock cycle. It uses 0.35-micron complementary metal-oxide semiconductor (CMOS)-integrated circuit technology and a fully pipelined 64-bit RISC architecture to provide the highest performance for Windows NT systems. The processor is housed in a 499-pin ceramic package and generates 28 watts of heat and is designed to work with the AlphaPC 164LX motherboard. The latest Alpha chips run at speeds of 833 megahertz (MHz) and higher.

Notes

Windows 2000 does not support the Alpha platform.

American National Standards Institute (ANSI)

A U.S. standards organization that facilitates and governs the development of standards in many areas, including computing and communication.

Overview

The American National Standards Institute (ANSI) was founded as a private sector voluntary standards association in 1918. It is a nonprofit private association with almost 1,400 member organizations.

ANSI does not create standards itself but oversees groups and organizations in the development of standards. ANSI is a member organization of the International Organization for Standardization (ISO) and provides the charter for the Institute of Electrical and Electronics Engineers (IEEE).

Standards that are approved by ANSI are called ANSI Standards. Examples include the ANSI C/C++ programming language standards, ANSI-89 SQL standards, and ANSI character set. ANSI has approved more than 13,000 standards to date.

Notes

ANSI is also used to refer to the ANSI character set.

American Registry for Internet Numbers (ARIN)

A nonprofit organization that administers the registration and allocation of numbers relating to the operation of the Internet in North and South America.

Overview

The American Registry for Internet Numbers (ARIN) was formed in 1997 through the joint efforts of the Internet Assigned Numbers Authority (IANA), the Internet Engineering Task Force (IETF), the National Science Foundation (NSF), and other organizations. ARIN exists primarily to provide a number of critical functions related to the operation of the Internet:

- It oversees the registration and administration of Internet Protocol (IP) addresses. This is probably ARIN's most important function, which it took over from IANA when it was formed in 1997. ARIN works diligently to conserve the pool of available IP addresses and determines the size and scope of blocks of IP addresses granted in response to requests. The careful maintenance of the IP address system is critical to the Internet's health, and ARIN works hard to ensure that the routing tables maintained on the core routers of the Internet remain manageable in size. Internet service providers (ISPs) can contact ARIN to purchase blocks of IP

addresses that they can then assign to their customers—ARIN does not supply individual IP addresses directly to individuals (the smallest block available from ARIN is 4096 hosts in scope).

- It is responsible for registration and management of autonomous system numbers (ASNs) to public and enterprise networks.
- It maintains a central routing registry to which network operators can submit and obtain information relating to routing across the Internet.
- It maintains the IN-ADDR-ARPA and IP6.INT inverse mappings for Domain Name System (DNS).

ARIN is actually only one of three Regional Internet Registries (RIRs) that handle the above functions for different parts of the global Internet. ARIN's areas of responsibility are the regions of North and South America, the Caribbean, and sub-Saharan Africa. The other two RIRs are

- **Reseaux IP Europeans (RIPE):** Responsible for Europe, the Middle East, and other parts of Africa.
- **Asia Pacific Network Information Center (APNIC):** Responsible for the Asia/Pacific region.

Notes

ARIN does not handle the registration of domain names but instead manages the underlying IP addresses for which domain names are friendly handles. There are also two delegated name registries within ARIN: the Brazilian Registry (RNP) and the Mexican Registry (NIC-Mexico).

For More Information

You can find ARIN at www.arin.net.

analog

Transmission of electrical signals that vary smoothly with time.

See: analog transmission

analog modem

A type of modem used for asynchronous transmission of information over Plain Old Telephone Service (POTS) telephone lines.

Overview

The word *modem* stands for modulator/demodulator, which refers to the fact that modems convert digital transmission signals to analog signals and vice versa. An analog modem performs this modulation, but a digital modem does not perform modulation and simply transports digital signals as they are. In effect the phrase “digital modem” is a misnomer because no modulation occurs, and “analog modem” can simply be termed “modem” instead.

To transmit computer data over a telephone channel, a modem modulates the incoming digital signal received from the computer into an analog signal whose frequency lies within the carrying range of analog phone lines (between 300 hertz [Hz] and 3.3 kilohertz [kHz]). To accomplish this, modulation of the digital signal from the computer with an analog carrier signal is performed. The resulting modulated signal is then transmitted into the local loop and carried over the Public Switched Telephone Network (PSTN) until it arrives at its destination station, where a similar modem demodulates the modulated analog signal into a stream of digital data that the remote computer can understand.

However, this basic modulation/demodulation process over POTS lines can transmit data only at speeds of

about 1,200 bits per second (bps). To achieve the much higher speeds of today’s modems, advanced technologies must be applied, including echo canceling, training, data compression, and special modulation algorithms such as quadrature amplitude modulation (QAM). Using these technologies, modem speeds of 56 kilobits per second (Kbps) are now common.

Bell Laboratories in the 1960s and 1970s originally formulated modem standards, but after the breakup of Bell Telephone, the task of developing modem standards was taken over by the International Telegraph and Telephone Consultative Committee (CCITT), which is now called the International Telecommunication Union (ITU). According to ITU specifications, modem standards are classified by a series of specifications known as the V series.

analog-to-digital converter (ADC)

Any device used for changing analog signals into digital transmission.

Overview

An example of analog-to-digital conversion is recording someone singing onto a CD. The pressure waves in the air produced by the vibration of the person’s vocal cords are analog in form and continually vary in strength within a certain range of values. The recording equipment samples this continually varying information at discrete time intervals and converts it to digital form.

Analog-to-digital converters (ADCs) are used in industry to convert environmental variables (temperature, pressure, density, speed, and so on) that vary continuously over time to digital information, which can then be analyzed using computer programs. ADCs are used in analog modems to convert digital signals into audio and vice versa.

See Also: analog, digital

analog transmission

Transmission of electrical signals that vary smoothly with time.

Overview

An analog signal can take on any value in a specified range of values as shown in the diagram. A simple example is alternating current (AC), which continually varies between about +110 volts and -110 volts in a sine wave fashion 60 times per second. A more complex example of an analog signal is the time-varying electrical voltage generated when a person speaks into a dynamic microphone or telephone. Analog signals such as telephone speech contain a wealth of detail but are not readily accessible to computers unless they are converted to digital form using a device such as an analog-to-digital converter (ADC). Old-fashioned vinyl records store sound information in the form of a continuously varying analog groove, but modern musical CDs store their information in digital form. Some people claim they can tell the difference between an analog and a digital recording and generally agree that the analog recording sounds “warmer.”

Analog transmission. Example of an analog transmission.

Analog signals are usually specified as a continuously varying voltage over time and can be displayed on a device known as an oscilloscope. The maximum voltage displacement of a periodic (repeating) analog signal is called its amplitude, and the shortest distance between crests of a periodic analog wave is called its wavelength.

anchor

In Hypertext Markup Language (HTML), a source or target of a hypertext link.

Overview

Anchor tags are the key feature of HTML that enables hypertext (linked documents) to be constructed. Without anchor tags, Web pages could not be linked together.

An anchor can be either text or a graphic and is specified using the tag formation `<A>...`. There are two types of anchor tag. The first type creates a hypertext link that refers to a document. For example, the following HTML element will display the word “contents” as a hyperlink. If the user clicks on the link, the browser will load the contents.htm page specified in this tag:

```
<A HREF="http://www.northwind.microsoft.com /
contents.htm">Contents</A>
```

The second type of anchor tag marks a portion of text as a destination for a hyperlink. You can place the following element at the end of the contents.htm page:

```
<A NAME="bottom">This is the end of the page</A>
```

To load the contents.htm page and jump directly to the bottom of the page, the user needs to click a hyperlink such as this one:

```
<A HREF="http://www.northwind.microsoft.com /
contents.htm#bottom">Contents</A>
```

announcement

A feature that enables Windows Media Player to receive streaming multimedia information.

Overview

An announcement’s function depends on whether the transmission method is multicasting or unicasting. If the transmission method is multicasting, announcements enable Windows Media Player to retrieve the channel file containing channel information. If the transmission method is unicasting, announcements supply the client with information on how to connect to the Windows Media Server.

Announcements, which are used only with Advanced Streaming Format (ASF) transmissions, are text files that have the extension .asx. Once created, an announcement can be distributed to clients by several means: over the Web, through e-mail, or on a network share.

Announcement Manager

A service in Microsoft Windows 98 that automatically runs in the background when you have WebTV for Windows installed on your computer.

Overview

Announcement Manager receives broadcast announcements from TV networks or Web sites that notify your computer about the time and address of the broadcast and which software applications must be running to receive the broadcast. When Announcement Manager receives an announcement, it directs it to the broadcast filters you have configured for your WebTV service. The broadcast filters then determine whether to ignore the broadcast or schedule its reception.

Announcement Manager is part of the Microsoft Broadcast Architecture, a specification for receiving Web information broadcast to your computer through a TV tuner interface.

anonymous access

An authentication scheme in which the user's identity is not verified.

Overview

Anonymous access is one of several authentication protocols supported by Microsoft Internet Information Services (IIS) and is strictly speaking not an authentication scheme at all because the users' credentials are not requested and, if supplied, are ignored. Anonymous access is typically used to allow anonymous users (that is, everyone) to gain access to public content hosted on a Web server. Anonymous access is typically used on low-security public Web sites where the identity of the person visiting the site is not important. By enabling anonymous access to the site, distrusted users from the Internet can access content on the site.

Anonymous access on IIS works by making use of a default anonymous user account called IUSR_machinename. This account is a local user account that is created during Setup and is used exclusively to authenticate anonymous users and grant

them access to resources on the machine. The IUSR_machinename account requires the Log On Locally system right in order to grant anonymous access to machine resources.

See Also: authentication protocol

anonymous user

Any user who attempts to access network resources without providing a username or password.

Overview

Some applications such as Microsoft Internet Information Services (IIS) can be configured to allow anonymous users to access their resources. This allows distrusted users from unsecure networks such as the Internet to access data that is made available for the public at large.

Access to network resources by anonymous users can be controlled by assigning permissions to a special anonymous user account IUSR_ComputerName. Windows 2000, Windows XP, and Windows .NET Server then provide anonymous users access to resources by impersonating the user utilizing the anonymous user account.

ANSI C/C++

A standard published by the American National Standards Institute (ANSI) for writing C and C++ code.

Overview

Programs written in ANSI C or ANSI C++ are portable to a large number of computing platforms. Most commercial C/C++ programming tools, such as Microsoft Visual C++, contain extensions to ANSI C/C++ that

simplify common programming tasks considerably but restrict the portability of the resulting code to different platforms.

You can use Visual C++ to write strict ANSI C/C++ code by following these guidelines:

- Call Win32 application programming interfaces (APIs) directly in your program instead of using the Microsoft Foundation Classes (MFC) libraries.
- Disable the Microsoft extensions to C++ by running Visual C++ using the `/Za` command-line option.
- Use the `isostream` and standard template libraries from the ANSI Standard C++ library and the appropriate `#include` statements in your code.

ANSI character set

An eight-bit character set developed by used by the American National Standards Institute (ANSI).

Overview

The ANSI character set uses 256 characters (numbered 0 through 255). The American Standard Code for Information Exchange (ASCII) character set is a subset of the ANSI character set with characters numbered 32 through 126, each representing a displayable character.

ANSI uses a single byte to represent a character, in contrast to the Unicode standard supported by Microsoft Windows NT, which uses 2 bytes to represent a character. For example, the ANSI character “A” would be represented in hexadecimal notation by the single byte 41h. ANSI’s 256-character limit supports only a few international characters, such as accented French and German vowels, but the Unicode’s 65,536-character limit supports virtually every alphabet in the world. For example, the Unicode character “A” would be represented in hexadecimal notation by the 2-byte string {41h, 00h}.

The following table shows which Windows environments support ANSI and Unicode for character encoding.

Windows Environments and Character Encoding

<i>ANSI</i>	<i>Unicode</i>
16-bit Windows object libraries	32-bit Windows object libraries
Windows 95 and Windows 98 API	Windows NT and Windows 2000 API Automation in Windows 95, Windows 98, Windows NT, Windows 2000, Windows XP, and Windows .NET Server

Notes

Some ANSI character codes cannot be displayed by Microsoft Windows applications and are generally displayed as solid blocks in the application interface.

answer file

A text file that can be used to perform an unattended installation of Microsoft Windows 2000.

Overview

In the answer file you specify in advance the answers to the user prompts that occur during a normal installation. These prompts can include specifications such as what keyboard layout to use, whether the computer should join a domain or belong to a workgroup, what network protocols should be installed, and so on. The answer file is invoked using the `/u` switch when running the `Winnt` or `Winnt32` setup utility. Answer files can be customized for individual machines by using Uniqueness Database Files (UDFs). The UDFs can be used to specify computer-specific parameters such as the computer name.

A sample answer file `Unattend.txt` is located in the `\I386` folder on the source CD. You can customize this file using Notepad or another text editor to suit your needs.

antenna

A device used to enhance the transmission and reception of radio signals.

Overview

A full treatment of antenna theory is beyond the scope of this book, and antenna considerations have only become an issue for local area network (LAN) administrators with the recent proliferation of wireless LANs (WLANs), wireless bridges, and wireless cellular data transmission technologies. Just a few issues and developments are considered here.

The first notebook computer to incorporate a built-in factory-installed antenna for wireless networking was the iBook from Apple Computer. The iBook uses the AirPort wireless networking technology, and although the antenna is included, an AirPort add-on card must be purchased to connect the machine to a WLAN. Other vendors such as Dell Computer Corporation have quickly followed Apple's lead in this area. PC board mountable antennae are often flat dielectrically loaded omnidirectional antenna and require no external tuning components.

For a wireless network to be effective, the base station also needs a suitable antenna. The range of antennae available for base stations is large, and the latest ones support multiband operation for the 900-megahertz (MHz) band, 2.4-gigahertz (GHz) Industrial, Scientific, and Medical (ISM) band, and 5-GHz UNI band.

A primary issue regarding antennas for wireless devices is placement. For transmission stations, this means placing antennas as high as possible—on the roof, for example—to ensure the widest possible area of coverage. For end stations, obstacles such as concrete walls and iron girders within buildings can absorb, scatter, and attenuate signals so that practical networking becomes difficult or impossible. To overcome this, more powerful transmissions can be used, but the strength of end-station transmissions are limited for health reasons.

Another issue regards whether unidirectional or omnidirectional antennas are used. For wireless bridges connecting networks in different buildings, unidirectional antennas are used and must be aligned properly with no line-of-sight obstructions. Mobile devices such as laptops, Personal Digital Assistants (PDAs), and cell

phones require omnidirectional antennas to function properly, particularly when roaming.

Anycast

A network service for delivering datagrams to any one server belonging to a group of servers on a network.

Overview

Anycast was first proposed in RFC 1546 as a way to direct a network request to the closest (in the network sense of hops) server in a set of mirrored servers for servicing the request. Because fewest hops may not necessarily mean the server that responds best (due to latency, throughput, and host load), other Anycast-related initiatives have arisen in the last few years. These initiatives include Application-Aware Anycast, Global IP-Anycast, Simple Internet Protocol Plus, and others.

AO/DI

Stands for Always On/Dynamic ISDN, a modified form of Integrated Services Digital Network (ISDN) that supports transmission of data over the ISDN control channel (D channel).

See: *Always On/Dynamic ISDN (AO/DI)*

AOL Instant Messenger (AIM)

A popular instant messaging service from America Online (AOL).

Overview

AOL Instant Messenger (AIM) is a free instant messaging service that boasts more than 84 million users worldwide. The service allows users to send messages instantly to other users online, receive alerts and bulletins, have online chat conversations, receive news and other information, share files, and perform other useful activities.

The current version of client software is AIM 4.3, which supports additional features including participating in online games and accessing your buddy list from any computer. AIM is available for various platforms

including Microsoft Windows and Windows CE, Mac OS, Linux, and PalmOS. AIM operates using AOL's proprietary AIM Protocol, and AIM competes with other popular Instant Messaging (IM) systems including Microsoft Corporation's MSN Messenger.

For More Information

You can download the current version of AIM from www.aol.com/aim.

MSN Messenger can be found at messenger.msn.com.

AP

Stands for access point, a device connected to a local area network (LAN) that enables remote wireless stations to communicate with the LAN.

Apache

Short for Apache Web server, an open-source Hypertext Transfer Protocol (HTTP) server whose code was developed and is maintained by the Apache Software Foundation.

Overview

Apache started out as a patch for the original National Center for Supercomputing Applications (NCSA) httpd server—hence the new server was “a patchy” server. The NCSA httpd server was stuck at version 1.3 and had some security issues, and so a group of people took the 1.3 code, which was in the public domain, and patched it. The group later rewrote most of the base code from scratch in order to support external modules written in C language.

One of the Apache platform's strengths is its modular design, which consists of a central Apache kernel interacting with various code modules that provide additional functionality. This architecture speeds the development cycle and makes it easy for third-party developers to build custom modules to meet their needs and compile them into the Apache source.

Security is a top priority for administrators who run Web servers, and Apache includes support for a number

of advanced security features through various security modules:

- **Access control:** The default security setting for Apache is “deny all,” after which selective access can be provided to specific users through the `Access.conf` file.
- **Authentication:** Apache supports basic authentication using a number of password file formats, starting with `/bin/htpasswd`. Modules are also available for host-based authentication where access is granted based on Internet Protocol (IP) address and anonymous access using a user's e-mail address as a password.
- **Encryption:** Support for Secure Sockets Layer (SSL) encryption in Apache is provided by free-ware packages such as `Apache-SSL` and `mod_ssl`, and by commercial packages such as `Stronghold` from C2Net Software.
- **Logging:** Apache includes support for comprehensive logging of server events. Logs are kept in two files, `access_log` and `error_log`.

Apache is one of the most popular Web servers in use, with an estimated more than 6 million Web sites deployed on it. Some market watchers estimate that about 60 percent of all Web servers are running Apache. Apache is widely deployed wherever UNIX is found, including universities and large enterprise networks, and is available for more than a dozen different operating system platforms, including Microsoft Windows.

Notes

The most common vulnerability of Apache servers is running the core process using root privileges. This makes the server vulnerable to what is called a “root exploit,” which can allow a malicious remote user to run Common Gateway Interface (CGI) scripts using root privileges. The way to avoid this is to include the following lines in the `Httpd.conf` configuration file:

```
user nobody
```

```
group nobody
```

Apache Software Foundation

An open-source community guiding the development of the Apache Web server and other open-source tools and programs.

Overview

The Apache Software Foundation, formerly the Apache Group, is a nonprofit organization that provides legal, organizational, and financial backing toward the development of open-source software projects that use Apache Web server software. Some of the projects the foundation is working on include

- Apache Server
- Apache XML Project-Apache
- Jakarta
- Java-Apache
- mod_perl
- PHP
- Apache Tcl

Apache XML Project

An initiative of the Apache Software Foundation to create open-source tools for developing Extensible Markup Language (XML) business solutions.

Overview

The Apache XML Project is an initiative with three goals:

- Developing tools for creating commercial-class XML-based business solutions that are standards-compliant and follow the open source model.

- Provide helpful feedback to the World Wide Web Consortium (W3C) and other bodies involved in the development of XML standards.
- Provide XML resources for other initiatives of the Apache Software Foundation.

Several commercial companies have contributed technology to this initiative, including Sun Microsystems, IBM, and Lotus Software (formerly Lotus Development Corporation, now part of IBM), and other contributors have come from the Open Source community at large.

Some of the subprojects within this initiative include

- **Cocoon:** XML-based Web publishing using Java.
- **FOP:** Extensible Stylesheet Language (XSL)–formatting objects using Java.
- **Xalan:** XSL Transformation (XSLT) stylesheet processing using Java and C++.
- **Xang:** Dynamic server pages using Java.
- **Xerces:** XML parsing using Java, C++, and Perl.

API

Stands for application programming interface, any collection of programming routines and functions that an application can use to access low-level machine services.

See: *application programming interface (API)*

APIPA

Stands for Automatic Private IP Addressing, a feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that enables machines to be automatically assigned Internet Protocol (IP) addresses without the use of Dynamic Host Configuration Protocol (DHCP).

See: *Automatic Private IP Addressing (APIPA)*

APM (Advanced Power Management)

Stands for Advanced Power Management, a legacy specification for power management of computer hardware.

See: Advanced Power Management (APM)

APM (Application Performance Management)

Stands for Application Performance Management, a set of technologies, business processes, and services for guaranteeing what subscribers experience from service providers.

See: Application Performance Management (APM)

APNIC

Stands for Asia Pacific Network Information Center, the counterpart of American Registry for Internet Numbers (ARIN) and the agency responsible for administering the registration and allocation of Internet numbers for the Asia/Pacific region.

See: Asia Pacific Network Information Center (APNIC)

APPC

Stands for Advanced Program-to-Program Communications protocol, a set of protocols developed by IBM that enables transactional programs to communicate with each other.

See: Advanced Program-to-Program Communications (APPC) protocol

APPC File Transfer Protocol (AFTP)

A protocol that provides file transfer capabilities for the Advanced Program-to-Program Communications (APPC).

Overview

APPC File Transfer Protocol (AFTP) servers are the APPC equivalent of File Transfer Protocol (FTP) servers

in the Transmission Control Protocol/Internet Protocol (TCP/IP) world. Microsoft SNA Server can be used to establish AFTP connections to AS/400 or mainframe computers running the APPC applications suite. Users can then utilize standard FTP client software to transfer files between the SNA server and the AS/400 or mainframe host. The optional AFTP service must first be installed on the SNA server. The installation can be configured so that the SNA server performs the function of an FTP-to-AFTP gateway. This will enable standard FTP clients to transfer files to and from the mainframe host.

Apple Open Transport

An Apple networking technology for transport-independent networking that is part of the networking and communication subsystem of the Apple Macintosh operating system.

Overview

Apple Open Transport is designed to make it easy to set up and configure networking on the Macintosh computer and to increase the performance of file, print, and other networking services on a MacOS server. Open Transport provides a consistent interface for configuring network services across supported protocols and a uniform set of application programming interfaces (APIs) for accessing networking and communication services on the Macintosh.

Open Transport enables protocols to be loaded and unloaded on demand, provides a networking naming scheme plus consistent network services over the Transmission Control Protocol/Internet Protocol (TCP/IP) and AppleTalk protocols, and includes support for TCP/IP services such as Dynamic Host Configuration Protocol (DHCP) and Domain Name System (DNS). Open Transport also provides consistent API access to serial communication on the Macintosh, while third-party support is available for Point-to-Point Protocol (PPP), Network Control Protocol over Internetwork Packet Exchange (NCP/IPX), Server Message Block over Transmission Control Protocol (SMB/TCP), NetBIOS, DECnet, LAT, and X.25.

The Open Transport/AppleTalk protocol stack supports both the dynamic self-addressing of traditional AppleTalk clients and newer manually assigned static addressing. The Open Transport/TCP/IP protocol stack supports DHCP, bootstrap protocol (BOOTP), both local hosts files and DNS, Internet Protocol (IP) multicasting, both Ethernet Version 2 and Institute of Electrical and Electronics Engineers (IEEE) 802.3 framing, TCP wildcard source port assignments, Point-to-Point Protocol (PPP) connectivity, IP multihoming, and almost unlimited simultaneous TCP connections (limited only by installed memory and processor power).

Notes

An Apple Macintosh running Open Transport/TCP/IP can function as a DHCP client to a Microsoft Windows NT server running as a DHCP server, but not as a Windows Internet Naming Service (WINS) client.

AppleShare

The file sharing protocol for AppleTalk networks.

Overview

AppleShare provides the following functions:

- Enables sharing of volumes, folders, and printers
- Provides auditing information on which resources have been accessed
- Supports password-based control of access to shared resources

Notes

By installing Services for Macintosh on a Microsoft Windows 2000 server, the Windows 2000 server can emulate an AppleShare server so that Macintosh clients can access shared resources on the Windows 2000 server.

AppleShare IP

An Apple networking technology that supports native Transmission Control Protocol/Internet Protocol (TCP/IP) on the Apple Macintosh platform.

Overview

AppleShare IP provides Web, file, print, and e-mail services for departmental and workgroup-level environments. The latest version, AppleShare IP v6.1, features a single integrated administration console for local server management, remote administration using a standard Web browser, IP address filtering, Sherlock searching support, multihosting, Simple Mail Transfer Protocol (SMTP) and point of presence (POP) protocol support, shared Internet Mail Access Protocol (IMAP) folders, Domain Name System (DNS) services, and full compatibility with MacOS 8.5 and higher.

AppleShare IP client software must be installed on Macintosh client machines to enable them to access AppleShare IP services on a server over the network. AppleShare IP supports both Server Message Block (SMB) and File Transfer Protocol (FTP) protocols in addition to AppleShare file sharing, and is compatible with both Macintosh and Microsoft Windows clients.

applet

A program written using the Java programming language that can be accessed through a Web page and downloaded to the client machine, where it is run within the Web browser window.

Overview

Java applets can be used to add dynamic functionality to static Web pages provided users view these pages with a Java-enabled Web browser.

When an applet is created, its Java statements are compiled into an intermediate pseudo-machine-code language called a bytecode. The bytecode file is stored as a class file on a Web server such as Microsoft Internet Information Services (IIS), and a Web page can reference the class file using an <APPLET> tag. When a Web browser requests the page and encounters the <APPLET> tag, the bytecode in the class file is executed in a Java virtual machine on the browser.

AppleTalk

The original networking protocol for Apple Macintosh networks.

Overview

AppleTalk is a suite of networking protocols that work together to provide file and print sharing services to Macintosh networks. AppleTalk enables users to share folders and printers for access by other network users. AppleTalk is a legacy technology that has been largely replaced by Apple Open Transport, which supports AppleTalk, Transmission Control Protocol/Internet Protocol (TCP/IP), and other popular network protocols.

Architecture

AppleTalk is a workgroup-level networking technology that supports up to 254 network nodes per physical network. AppleTalk can run on top of the legacy LocalTalk data-link protocol, which was built into the Macintosh RS-449/RS-422 serial interface. In the more recent

AppleTalk Phase II, the data-link protocols supported include EtherTalk, TokenTalk, and FDDITalk for connectivity with Ethernet, Token Ring, and Fiber Distributed Data Interface (FDDI) networks, respectively.

Addresses of machines on AppleTalk networks are randomly self-assigned when the machine is first attached to the network and then broadcast to ensure they are not already being used. This dynamic addressing feature is based on the AppleTalk Address Resolution Protocol (AARP).

AppleTalk internetworks are logically partitioned into zones whose main function is to make network resources easier for users to access. A *zone* is a logical representation of AppleTalk network nodes that can span multiple physical networks. The mapping between zones and network numbers is maintained by the Zone Information Protocol (ZIP), which creates Zone Information Tables (ZITs) that are stored on AppleTalk routers.

appliance

A general term referring to any network-capable or Internet-capable computing device that can be deployed with plug-and-play ease.

Overview

The market for appliances ranges from home users to the largest enterprise. At the small end of the scale are Internet access appliances that allow users to connect home networks to the Internet using dial-up, digital subscriber line (DSL), or cable modem technologies. Many of these Internet access appliances include advanced features such as built-in firewalls, Web-based management consoles, built-in hubs, and so on.

At the larger end are appliances built for large companies and for service providers, for example:

- **Server appliances:** These include Web server appliances running Apache/Linux or IIS/Windows 2000 and file server appliances such as Cobalt's Qube and Compaq NeoServer. Server appliances are typically 1U or 2U rack-mountable devices and can often be set up in minutes or even seconds. These appliance servers fill specific needs for business, and their market is growing rapidly.
- **Storage appliances:** An example here is Novell's Network Attached Storage (NAS), a rack-mountable appliance that provides up to 1 terabyte of storage, supports all major server platforms, and has integrated Novell Directory Services (NDS) eDirectory and ZENworks management applications.

Application Center

One of Microsoft Corporation's new .NET Enterprise Servers, Microsoft Application Center is used for deploying and managing Web applications and Web services.

Overview

Application Center is a platform for deploying and managing high-availability Web applications and Web services. Application Center 2000 is built on the Microsoft Windows 2000 operating system platform and makes managing of clusters of application servers as easy as managing a single server.

Application Center provides simplified application management by allowing administrators to create logical groupings of application components and configuration information. These groupings can be easily managed, regardless of how they are deployed across the cluster, and changes made to one server in a cluster can be automatically applied to other servers. Migration and upgrading of applications can be automated, which simplifies the development cycle as applications are moved from test bed to production phase. Application Center is thus ideal for simplifying the staging and deployment of complex Web-based e-business applications.

Application Center provides built-in support for software scaling to increase the capacity of applications as the business need arises. This is possible through the underlying reliance on clustering technologies in which a group of servers is managed as a single resource, and Application Center simplifies and accelerates the deployment of clusters over traditional clustered server platforms. Application Center also supports load-balancing technologies such as Network Load Balancing (NLB), Component Load Balancing (CLB), and third-party load balancing solutions. With Application Center, your Web applications have no single point-of-failure and consequently high availability and reliability.

Application Center provides the enterprise with mission-critical availability and allows any server in a cluster to be brought down without affecting the integrity or operation of the applications running on the cluster. Application Center includes tools for monitoring cluster health and supports browser-based remote administration. Automated event response allows corrective action to be taken automatically when a component or server fails, without the need for human intervention.

application layer

The top layer (Layer 7) of the Open Systems Interconnection (OSI) reference model for networking.

Overview

The application layer is the layer in which network-aware, user-controlled software is implemented—for example, e-mail, file transfer utilities, and terminal access applications. The application layer represents the window between the user and the network and translates between the user running the application and the presentation layer (Layer 6). In the OSI model the application layer is also responsible for integrating the functionality of different applications together and determining the availability of resources.

Examples of protocols that operate at the application layer include File Transfer Protocol (FTP), Hypertext Transfer Protocol (HTTP), telnet, and similar protocols that can be implemented as utilities the user can interface with.

Notes

Originally the OSI model consisted of two kinds of application layer services with their related protocols:

- **Common Application Service Elements (CASE):** These enable users to initiate or terminate peer (Layer 7 to Layer 7) connections between different machines on the network, enable reliable transfer of information between them, initiate remote operations, and support recovery from failure and rollback steps.
- **Specific Application Service Elements (SASE):** These can include file transfer, message handling, terminal access, and other services that make use of the CASE elements and protocols.

These terms have largely been replaced with the term Application Service Elements (ASE) to describe the elements of the application layer. Note also that in most real-world networking, such as Transmission Control Protocol/Internet Protocol (TCP/IP) networking, these application layer services have no meaning.

application layer proxy

Any service or server that acts as a proxy for client computer requests at the application's protocols.

Overview

Application layer proxies provide security by hiding internal network addresses from the outside world. An example of an application layer proxy is illustrated in Microsoft Proxy Server. Here the Web Proxy Service is an application layer proxy for the Hypertext Transfer Protocol (HTTP), Secure Hypertext Transfer Protocol (S-HTTP), and File Transfer Protocol (FTP). Microsoft Proxy Server can grant users access to selected application layer protocols and can restrict access to remote Web sites by domain name, Internet Protocol (IP) address, and subnet mask.

Application layer proxies provide more support for the additional capabilities of each protocol than circuit layer proxies do. For example, application layer proxies can support virus scanning. Application layer proxies are also client-neutral and require no special software components or operating system on the client computer to enable the client to communicate with servers on the Internet using the proxy server.

See Also: *proxy server*

application level gateway

A type of firewall that provides application-level control over network traffic.

Overview

Application level gateways examine incoming packets at the application level and use proxies to create secure sessions with hosts on the other side of the firewall. For example, when an external user with a Web browser tries to access the company's internal Web server, the application level gateway runs a proxy application that simulates the internal Web server. A session is established between the remote user and the proxy application, while a separate, independent session is established between the proxy application and the internal Web server. The remote user makes a request to the proxy, the proxy acts as a go-between and obtains the information from the internal web server, and then the proxy returns the result to the remote user.

The advantage of using application level gateways over packet-filtering routers is that although in packet

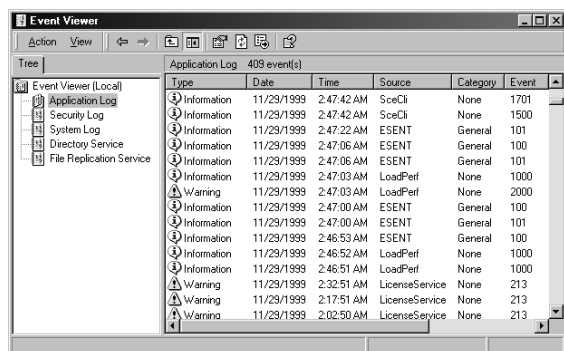

filtering a direct network connection still exists between the remote user and the internal network resource, an application level gateway prevents the remote user from directly accessing the internal network resource. This layer of additional security comes at some cost—namely, that application gateways are generally slower and require a separate proxy application for each internal network service you want to make available through the firewall. These proxy applications are sometimes known as translation agents because they enable an application on one side of the firewall to connect with a similar or complementary application on the other side.

Application gateways are typically used to deny access to the resources of private networks to distrusted users over the Internet. Application level gateways can operate across firewalls or routers using Network Address Translation (NAT), but they must be configured to do so on an application-by-application basis.

application log

A Microsoft Windows 2000, Windows XP, and Windows .NET Server log that records events generated by applications running on the system.

Application log. Displaying the application log in the Event Viewer console.

Overview

You can view and manage the application log using Event Viewer, and it can contain three types of events:

- **Error event:** Indicated by a red stop sign and signals a serious condition, such as a failed service

- **Warning event:** Indicated by a yellow warning sign and signals a potentially serious condition, such as low disk space
- **Information event:** Indicated by a blue information sign and signals a noteworthy event, such as a service successfully starting up

Microsoft BackOffice applications typically log events to the application log. Administrators should review the application log regularly to ensure that applications are running properly. The screen capture shows the application log as viewed by the Event Viewer management console for Windows 2000.

Application Performance Management (APM)

A set of technologies, business processes, and services for guaranteeing what subscribers experience from service providers.

Overview

Application Performance Management (APM) carries Service Level Agreements (SLAs) to the next level, providing a model for guaranteeing the end-user experience for customers of application service providers (ASPs). To accomplish this, APM integrates a number of business models and services:

- Traditional help desk services for problem resolution.
- Monitoring of SLAs.
- Network and system management tools working at the application level.
- Professional services to handle serious IT (information technology)–related crises.
- Services for processing management data.
- Support and training services.

A service provider that specializes in APM is sometimes referred to as a management service provider (MSP).

See Also: *application service provider (ASP)*

application programming interface (API)

Any collection of programming routines and functions that an application can use to access low-level machine services.

Overview

When you write applications for a high-level operating system such as Microsoft Windows, you use standard Windows application programming interfaces (APIs) to access standard operating system and networking services and functions. One application can then issue an API call to another application in order to execute that API function. Details of APIs are primarily of interest to developers.

Windows operating systems provide predefined sets of APIs for various purposes, such as Telephony Application Programming Interface (TAPI) for accessing functions related to making voice, data, or fax calls; Messaging Application Programming Interface (MAPI) for messaging functions; and so on.

An example of an API function in Windows NT is NetServerEnum. When a computer on a network issues a net view command to obtain the list of resources or computers that can be accessed using Network Neighborhood or Windows Explorer, the client computer issues a NetServerEnum API call to the Computer Browser service.

Microsoft Windows platforms include two basic sets of APIs:

- **Win16:** These 16-bit APIs were used by Windows 3.1.
- **Win32:** These 32-bit APIs are used on Windows 95, Windows 98, Windows Millennium Edition (Me), Windows NT, Windows 2000, Windows XP, and Windows .NET Server.

Notes

API also represents any set of calling conventions in a programming language that specifies how such a service is invoked through an application. Application programming interfaces (APIs) let C and assembly language routines interact with services and programming tools.

application service provider (ASP)

A general term for a company that offers software services to business customers across the Internet, particularly services involving outsourcing of Web and e-business applications.

Overview

A simple way of understanding the application service provider (ASP) model is to consider an ASP to be a company that hosts software applications for client companies and delivers them using the Internet for a monthly service fee. These applications are typically Web-based applications accessed by clients through a simple Web browser, although other delivery methods may be used, including Windows 2000 Terminal Services and Citrix MetaFrame. Once a client leases an application, the ASP is then responsible for day-to-day administration of the application and for maintenance and upgrades. ASPs may also be responsible for storing client data as well, although companies performing this service are more commonly called Storage Service Providers (SSPs). In contrast with simple Web hosting companies that offer their clients access to database applications and scripting tools but little else, ASPs also host the client's business logic and data at their remote data centers and provide a full range of supporting services to the client.

ASPs generally target one of two different market areas:

- **Vertical-market ASPs:** These target small to medium-sized business (the SMB, or small-to-medium business, segment of the market) by offering them packaged services such as Internet/Intranet hosting, e-mail and workflow applications, and scaled-down Customer Relations Management (CRM) and Enterprise Resource Planning (ERP) applications. Some small companies might not have the resources even to hire a single full-time IT (information technology) person, yet by using an ASP, they can quickly and easily obtain and use the necessary Line-Of-Business (LOB) applications they need to compete in the Internet economy in a cost-effective fashion. ASPs targeting this market tend to offer one-size-fits-all applications based on business logic templates that offer few

customization options. This approach is taken to reduce costs for the ASP and make servicing this market level profitable.

- **Horizontal-market ASPs:** These target enterprise-level customers and offer similar applications but with more customization to fit these customers' needs.

When the ASP craze took off in 1999, most ASPs were dot-com startups targeting the small to mid-sized business market, which was itself growing rapidly due to the dot-com revolution then underway. The ASP revolution was driven largely by the increasing shortage of IT professionals in the marketplace which left hundreds of thousands of IT positions unfilled, the rapid proliferation of new IT technologies based on the Internet, and by the proliferation of dot-com startups that needed to deploy business applications and to deploy them fast in the highly competitive Internet economy of the late 20th century. But with the dot-com crash of 2001 many of the ASPs failed as their market space dried up, and some survivors instead began targeting large enterprises by offering the application customization these businesses required. The attraction of these enterprise-level customers for ASPs is their long-term stability and broad capital base, but such clients tend to be more conservative in their outlook and more cautious about embracing new service models. Meanwhile, large software companies such as Microsoft Corporation and Oracle Corporation began to reposition themselves as service providers instead of software vendors. With their proven track record and large resources, many analysts expect these large companies to dominate the ASP business in a few years, with smaller companies focusing on niche areas where their services can be most effectively marketed. Furthermore, companies such as Microsoft and Oracle are developing a next generation of Web-enabled software that can be easily deployed by new ASP startups without the extensive customization required by the earlier generation of ASP applications. A good example is Microsoft Exchange 2000, which is an ASP-ready platform for providing Web-based messaging and collaborative applications.

When the ASP market was just emerging, the major attraction for customers was saving money. As the

market began to mature, other issues became important for customers to consider when shopping for an ASP:

- **Security:** In the beginning, many ASPs failed to address security concerns adequately. This has changed considerably, and the current generation of ASPs offers a full range of authentication and public-key infrastructure (PKI) services, virtual private networks (VPNs), firewall services, virus protection services, and intrusion detection services. Make sure the ASP you select can provide the level of security your company needs for its data.
- **Availability:** Make sure you negotiate a suitable service-level agreement (SLA) with your ASP to ensure that should their services be interrupted or terminated unexpectedly your business will still be able to function. If some of your staff will need to access ASP applications remotely using mobile clients through a VPN, make sure your SLA has a connectivity clause as well.
- **Performance:** Web-based applications mean high-bandwidth requirements for proper performance, both at the client end (usually T-1 or higher connections) and at the ASP's data center. Look for ASPs that colocate their servers at major Internet service providers (ISPs) for best performance and that have multiple redundant connections to the Internet with sufficient bandwidth to support the number of customers they service.
- **Track record:** With many of the first generation ASP startups having failed, companies are developing a "once-bitten, twice-shy" attitude towards outsourcing mission-critical business applications to ASPs. Talk to some of the ASPs larger clients and ask to see their financials to ensure their long-term viability before committing to using their services. When they start up, ASPs typically invest huge amounts of money in data centers, and they need to recover this investment quickly in order to survive. Some tier-1 Internet infrastructure providers offer ASP-level services, and these do not have as much of a capital risk associated with data center buildout as does a startup ASP.

Architecture

The data center is the heart of an ASP. Data centers are often colocated at ISP Points of Presence (POPs) to provide optimal high-speed connections to the backbone of the Internet. Data centers typically contain the following:

- File servers and database servers for storing structured data.
- Directory servers, Domain Name System (DNS) servers, and authentication servers for managing domains.
- Clustered or load-balanced Web servers for hosting Web applications in a redundant fashion.
- Terminal servers for supporting remote administration by customers.
- Storage area networks (SANs) and network attached storage (NAS) for storing data.
- Backup servers for archiving company data.

Advantages and Disadvantages

The advantages for client companies using ASPs are numerous and compelling to the management departments of most companies:

- They do not need to purchase the software themselves, which saves considerably on up-front costs.
- They do not need to hire additional IT staff to deploy and manage the new applications, which means considerable savings on labor costs.
- They can get new LOB applications up and running in a few days or weeks by relying on the expertise and infrastructure of the ASPs they are leasing these applications from.

The disadvantages of using ASPs are also important to consider when you are looking to outsource your LOB applications:

- You lose direct control over your company's software infrastructure and sometimes your data. This may be an issue with companies for which security is a strong concern.

- Many ASPs are new startups that may be acquired in the near future by larger companies or may fail if managed poorly. When your ASP fails, you might be left hanging with no software infrastructure to support your company's operations.

Marketplace

Some of the larger independent ASPs that have established themselves in the marketplace recently include the following:

- USinternetworking (www.usi.com)
- Corio (www.corio.com)
- Interliant (www.interliant.com)

Prospects

Although some industry watchers are predicting that the shakeout in the fledgling ASP industry will continue until only a few major players remain, the ASP model for outsourcing IT services has undeniably changed the IT landscape forever, as companies seek for cost-effective ways to economize on software purchasing by leasing LOB applications instead of purchasing them or developing them in-house.

One sector of the IT economy hit hard by the ASP revolution are the old-guard Independent Software Vendors (ISVs) that have spent years building and enhancing their line of client/server business applications. The Enterprise Resource Planning (ERP) industry has been one of the hardest hit, and established ERP vendors have had to move quickly to Web-enable their products and offer them as services in order to compete with upstart ASPs offering similar services. Some examples of ERP vendors who have repositioned themselves as ASPs include the following:

- SAP, with its SAP Hosting services
- PeopleSoft, with its eCenter
- Oracle, with its Oracle Business Online

Although the first two years of the new millennium have seen the demise of many ASP startups, industry analysts still predict strong growth in the ASP sector. The sector had a total worldwide market value of \$300 million in 1999 and some analysts predict this could

grow to as much as \$25 billion by 2004. Much of the success or failure of this growth depends on broadband Internet access becoming cheap and ubiquitous at all business levels.

Nevertheless, because things change so fast in the new Internet economy, it is hard to know whether to trust long-term predictions such as these. After all, the ASP market went from infancy to maturity in about a year, so five years seems like a long time to predict its future growth and evolution!

Notes

Other terms used by different vendors to describe the ASP model include hosted applications, e-services, and “software as a service.”

For More Information

You can find an ASP to meet your company’s needs using the ASP portals WebHarbor (www.webharbor.com) and ASPScope (www.aspscope.com).

For the latest news on the ASP industry, see ASPNews (www.aspnews.com) and ASPPlanet (www.aspplanet.com).

An established source of independent information for the ASP community is ASPI, the ASP Industry Consortium (www.aspindustry.org). This consortium has taken on the role of policing the rapidly growing ASP market, whose companies range from responsible to vendors of snake oil. ASPI has defined a series of best practices that new ASPs should follow as guidelines for responsible success.

A notable company that provides a meta-infrastructure that enables new ASPs to grow and flourish is Loudcloud (www.loudcloud.com), a brainchild of Marc Andreessen of Netscape fame.

archive attribute

An attribute of files and folders that is used for managing backups.

Overview

When an archive bit is marked or set for a file by a backup program, it indicates that the file or folder has been backed up. Then, when the backup program is run again, if the archive bit is still set, the file is not backed up because it has not been modified. If the file is modified in the interim, the archive attribute is cleared, indicating that the file needs to be backed up again.

In Microsoft Windows you can also manually set or clear the archive attribute for a file by opening the file’s property sheet.

See Also: *backup*

archiving

The process of long-term storage of important data for security and recovery reasons.

Overview

Archived data is usually stored in a compressed format because it is not required frequently. Some of the files that a Microsoft Windows 2000 administrator might consider archiving regularly include

- Event log files for the system, security, and application logs
- Performance monitor files for monitoring trends in memory, disk, processor, and network usage over time
- Log files for applications such as Microsoft Internet Information Services (IIS)

Notes

When you archive event log files, you can save these files in log file format, text file format, or comma-delimited text file format. An event’s actual binary data is saved only if you archive it in event log format, but saving the information in a comma-delimited text file format allows you to import these logs into a spreadsheet program to analyze trends.

ARCNET

Stands for Attached Resource Computer Network, an early local area network (LAN) architecture.

Overview

ARCNET was developed in 1976 by Datapoint Corporation and became an American National Standards Institute (ANSI) standard in 1982. ARCNET predates Ethernet by several years and can be implemented using a variety of media including RG/62 93-ohm coaxial cabling, RS-485 unshielded twisted-pair cabling, or fiber-optic cabling. ARCNET is a baseband networking technology that is similar to standards for token-passing bus networks running over broadband cabling. ARCNET uses a token-passing bus architecture with nodes forming a logical ring but a physical bus or star pattern. The core of an ARCNET network is a device called an active hub. Each of these hubs can support up to four connected devices. Multiple active hubs can then be interconnected using coaxial cable to support a maximum of 255 stations.

Classic ARCNET carries data at a rate of 2.5 megabits per second (Mbps). On coaxial cable, ARCNET cable runs can be up to 2000 feet (600 meters), but unshielded twisted pair supports distances of 400 feet (120 meters) and fiber-optic cabling distances of 8000 feet (2440 meters). A newer implementation called ARCNET Plus operates at a data rate of 20 Mbps and can support a maximum of 2047 nodes.

Notes

ARCNET is a legacy LAN technology occasionally found in some older networks.

Microsoft Windows 95, Windows 98, and Windows NT all support ARCNET. Sometimes a computer running Windows NT on an ARCNET network will have difficulty communicating with computers running Windows 95 and Windows 98 on the same network. This is because Windows NT uses Raw ARCNET and Windows 95 and Windows 98 use Encapsulated ARCNET. The workaround solution is to install the 16-bit Transmission Control Protocol/Internet Protocol (TCP/IP) stack with Novell Open Data-link Interface (ODI) drivers on the machines running Windows 95 and Windows 98.

ARC path

Stands for Advanced Reduced Instruction Set Computing (RISC) path, a syntax for naming partitions.

Overview

ARC paths are used in the Boot.ini file of Microsoft Windows 2000, Windows XP, and Windows .NET Server. The ARC path specifies the location of the partition that contains the Windows 2000 operating system files. In other words, the ARC path locates the system partition on the machine.

A typical ARC path on a Windows 2000 system might be the following:

```
multi(0)disk(0)rdisk(0)partition(1)\
WINNT="Microsoft Windows 2000 Server"/fastdetect
```

In the above statement:

- Multi(0) indicates that the system is using Integrated Device Electronics (IDE), Enhanced Small Device Interface (ESDI), or Small Computer System Interface (SCSI) drives and that it relies on the computer basic input/output system (BIOS) to load system files using INT 13 BIOS calls. The number in parentheses here should always be 0.
- Disk(0) is always zero when multi() is used; otherwise it refers to the physical disk when scsi() is used instead of multi(). Multi() means that Windows 2000 must use the system BIOS to load system files, and scsi() means that a SCSI device driver must be loaded to access the boot partition.
- Rdisk(0) indicates that the ordinal number for the system disk is 0. This value is usually between 0 and 3.
- Partition(2) indicates the number of the partition where the system files are located.

ARP

Stands for Address Resolution Protocol, the Transmission Control Protocol/Internet Protocol (TCP/IP) network layer protocol responsible for resolving IP addresses into MAC addresses.

See: *Address Resolution Protocol (ARP)*

ARPANET

Stands for Advanced Research Projects Agency Network, a U.S. Department of Defense project begun in 1969 that was designed to provide high-speed network communication links between supercomputers located at different sites around the country.

Overview

ARPANET was a test bed for the development of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite. The first node on the ARPANET was established in 1969 at UCLA. Soon afterward, more nodes were created at other institutions, including Stanford University and BBN Technologies. The first Request for Comments (RFC) was proposed in the same year by Steve Croker and was entitled "Host Software."

By 1971, ARPANET had grown to over 20 hosts, including MIT, NASA, and the RAND Corporation. The first international nodes were established two years later in Norway and England. In 1983, Military Network (MILNET) was split off from ARPANET, and TCP/IP officially became the standard protocol for ARPANET, at which time ARPANET started to become widely known as the Internet. ARPANET continued to evolve until NSFNET was established in 1986.

ARPANET was finally shut down in 1989.

Arp command

A Transmission Control Protocol/Internet Protocol (TCP/IP) utility for viewing and modifying the local

Address Resolution Protocol (ARP) cache, which contains recently resolved MAC addresses of Internet Protocol (IP) hosts on the network.

Overview

When one host on a TCP/IP network wants to communicate with a second host, the first host begins by using the ARP to resolve the IP address of the second host into its associated MAC address. The MAC address is needed for communication to take place over the network.

Typing `arp -a` displays the MAC addresses of recently resolved IP addresses. A sample display could be

```
Interface: 172.16.8.50
Internet Address      Physical Address      Type
172.16.8.25           00-20-af-b4-a1-4e     dynamic
172.16.8.200          00-40-95-d1-29-6c     static
```

One of these entries is static, meaning the Internet Protocol-to-MAC address mapping has been manually added to the ARP cache using `arp -s`.

AS/400

Stands for Application System/400, a midrange IBM server computing platform for business computing.

Overview

IBM's AS/400 platform is a 64-bit Reduced Instruction Set Computing (RISC) system available in a variety of configurations for different business needs. Until recently seen as a legacy platform similar to mainframes, AS/400 has been revamped in the last few years and is now one of the leading Web application and e-business platforms available for an enterprise.

AS/400 uses the OS/400 operating system but includes support for UNIX through the Portable Application

Solution Environment (PASE). Systems Network Architecture (SNA) support is also available for providing connectivity with IBM mainframe computing environments.

Some of the popular configurations in which AS/400 is offered include

- **AS/400e Model 250:** An entry-level single-processor machine with no support for logical partitioning. Suitable for running packaged Web applications for small businesses.
- **AS/400e Model 820:** A mid-tier four-way symmetric multiprocessing (SMP) server supporting up to 16 gigabytes (GB) of RAM and 4 terabytes of storage.
- **AS/400e Model 840:** Top-of-the-line enterprise-level server for high-transaction, high-volume e-business, supply chain and Enterprise Resource Planning (ERP) applications, supporting up to 24-way SMP, 96 GB of RAM, and up to 18.9 terabytes of storage.

Notes

The newest offerings in IBM's AS/400 line incorporate IBM's new high-performance copper-wired chips.

ASCII

Stands for American Standard Code for Information Interchange, a widely accepted system for coding U.S. English text using numeric values.

Overview

The purpose of ASCII is to allow human-readable documents to be stored and processed as binary information by computers. ASCII assigns a unique numeric value to each lowercase and uppercase alphabet letter, number, punctuation mark, and to certain other characters. For example, the capital letter "A" has the ASCII code 65 and a blank space has the code 32.

ASCII is a 7-bit character set that is the same as the first 128 characters (numbers 0 to 127) of the American

National Standards Institute (ANSI) character set. The following table shows the various characters in the ASCII character set. The first 32 characters are non-printing control characters that can be executed from the keyboard by using the Control key combined with other keys.

Notes

When you download files using File Transfer Protocol (FTP), you can choose whether to transfer the files as binary files or text files (ASCII files). Use only the ASCII file setting when downloading plain text files; otherwise, files will not be correctly transferred.

Some people create e-mail signatures for themselves using ASCII text characters, a practice called ASCII art. If you have the time and want to become an expert at this, read the FAQs (frequently asked questions) on the Web at non.com/news.answers/ascii-art-faq.html.

ASCII file

A file that contains unformatted American Standard Code for Information Interchange (ASCII) text.

Overview

An ASCII (text) file contains only characters, numbers, punctuation, tabs, and carriage return characters. You can create and edit an ASCII file using Microsoft Notepad. If you save it with the extension .txt, it is usually referred to as a text file, but you can save it with other extensions such as .bat or .cmd for batch files and .ini for initialization files.

Uses

ASCII files are often used for logon scripts and other batch files. Another common use is storing configuration information for operating systems and applications. Microsoft Windows 3.1 platforms used ASCII files for storing system and software configuration settings. These configuration files have the extension .ini and are referred to as INI (initialization) files. More recent Windows operating systems save this information in the registry. Most versions of the UNIX operating system still store their configuration settings in ASCII files.

Because ASCII files contain unformatted text, they can be read and understood by any platform and are useful for sharing information between platforms and between applications. Shared information is often saved in a comma-delimited text file, or .csv file, with the fields separated by commas. Microsoft Exchange Server can export mailbox properties and other information in .csv files, which can then be imported into spreadsheet programs such as Microsoft Excel for manipulation and analysis.

Asia Pacific Network Information Center (APNIC)

A counterpart of the American Registry for Internet Numbers (ARIN), this is the agency responsible for administering the registration and allocation of Internet numbers for the Asia/Pacific region.

Overview

The Asia Pacific Network Information Center (APNIC) is one of the three Regional Internet Registries (RIRs) that provide Internet numbers allocation and registration services to support the operation of the global Internet. These Internet numbers include IPv4 and IPv6 addresses, autonomous system (AS) numbers, and reverse Domain Name System (DNS) delegations. APNIC is responsible for allocation of these numbers for the Asia Pacific region, which comprises 62 different economies.

APNIC is a nonprofit, membership-based organization whose members include National Internet Registries, Internet Service Providers (ISPs), and similar bodies. Membership in APNIC is fee-based.

ASP.NET

The evolution of Microsoft Corporation's Active Server Pages (ASP) technology for the new .NET platform.

Overview

ASP.NET is an advanced platform for developing Web applications, Web Services, and Web Forms under the Microsoft .NET platform. ASP.NET solutions can be developed using Microsoft Visual Studio .NET and other tools, and ASP.NET supports application authoring in C#, Visual Basic .NET, and other programming languages.

ASP.NET is Microsoft's successor to ASP and ASP+ (Active Server Pages Plus) and is to a large degree backward-compatible with the syntax of these earlier platforms. Unlike ASP and ASP+, however, ASP.NET is a compiled platform rather than an interpreted one, which offers better run-time performance. ASP.NET is also easily factorable so that developers can remove modules that are not required for a particular application, making applications more code-efficient and giving them a smaller footprint.

ASP.NET provides two levels of programming models:

- **Low-level:** ASP.NET provides a programming model similar to Internet Server Application

Programming Interface (ISAPI) but easier to use for rapid development.

- **High-level:** ASP.NET enables the easy building of Web Forms, a high-level programming model for building Web applications.

ASP.NET also supports a number of different authentication schemes including Basic, authentication, Digest authentication, NT Lan Manager (NTLM) authentication, custom cookie-based authentication, and Microsoft Passport authentication.

Association for Computing Machinery (ACM)

The oldest and largest educational and scientific computing society in the world.

Overview

The Association for Computing Machinery (ACM) provides a forum for the exchange of information, ideas, and discoveries relating to many aspects of computing. The ACM has a worldwide membership of 80,000 computer professionals representing a wide variety of interests. The ACM sponsors a number of special interest groups (SIGs) that bring together ACM members with shared interests. These SIGs publish technical newsletters, host conferences, and help develop standards.

One SIG of interest to networking professionals is the ACM Special Interest Group on Data Communication

(SIGCOMM), which provides a forum for data communication professionals. SIGCOMM focuses on standards for network protocols and architectures. SIGCOMM publishes the ACM/IEEE Transactions on Networking Journal, sponsors conferences, and publishes a quarterly newsletter called the Computer Communication Review (CCR) in conjunction with the Institute of Electrical and Electronics Engineers (IEEE).

Asymmetric Digital Subscriber Line (ADSL)

A form of Digital Subscriber Line (DSL) technology that provides subscribers with high-speed voice and data services over twisted-pair copper phone lines.

Overview

Asymmetric Digital Subscriber Line (ADSL) was developed by Bellcore in 1989 as a means of transmitting digital information over ordinary twisted-pair Plain Old Telephone Service (POTS) telephone lines to subscribers at speeds faster than 1 megabit per second (Mbps). The original vision of ADSL was to provide residential subscribers with high-quality digital multimedia content, particularly Moving Pictures Experts Group (MPEG) movies through Video On Demand (VOD) services. This was intended to allow phone companies to compete with the emerging cable television market for delivering video to residential areas. This goal has since faded, and now the main push for deploying ADSL is residential broadband Internet access.

ADSL specifies how to implement high-speed, full-duplex transmission over the existing twisted-pair copper cabling of POTS. ADSL can be used to simultaneously transmit voice and data over a single telephone line and can be used to provide high-speed Internet access for both homes and businesses. Even should the data link to the Internet go down, POTS voice service would still be available using ADSL.

The *asymmetric* in ADSL refers to the fact that the upstream and downstream transmission rates in ADSL are not equal. Over best-quality copper phone lines, ADSL can achieve upstream speeds of up to 1.5 Mbps and downstream speeds of up to 9 Mbps, usually in a

10:1 ratio. This asymmetry makes ADSL ideal for providing high-speed Internet access to homes and businesses where fast download speeds are more important than upload speeds.

1. Typical ADSL Configuration

2. ADSL Bandwidth Allocation

Asymmetric Digital Subscriber Line (ADSL). Implementing ADSL.

Uses

ADSL has many advantages over standard analog modem access to the Internet, including much higher data rates, instant-on connection, simultaneous transmission of voice and data over a single phone line, and greater security. The negative side of ADSL is the higher equipment cost and the fact that customers must be located within 18,000 feet (5500 meters) of the carrier's CO for ADSL to work. ADSL Internet services typically cost between \$40 and \$100 per month, depending on the carrier and the area being serviced.

Besides providing residential and business Internet access, ADSL also has other uses, including the following:

- Connectivity with branch offices.
- B2B secure communications (using Point-to-Point Tunneling Protocol [PPTP] or Layer 2 Tunneling Protocol [L2TP]).
- Telecommuting.

An external ADSL modem with support for Network Address Translation (NAT) allows a single modem to connect a network of machines to the Internet using only one carrier-granted Internet Protocol (IP) address. Some ADSL appliances include a built-in Ethernet hub to make this process simpler.

Cable modem technologies are currently competing with ADSL in the residential broadband Internet access, but ADSL offers greater security than cable modems and provides guaranteed bandwidth that shared-network cable modems cannot currently provide.

Implementation

The great advantage of ADSL as a high-speed access service is the ubiquity of the existing twisted-pair POTS wiring system. ADSL providers do not have to build a delivery infrastructure because the wires are already there; they just have to install the switches and modems to make it work.

ADSL uses frequency-division multiplexing (FDM) to separate voice and data into three separate communications channels:

- A baseband voice channel
- An upstream data channel
- A downstream data channel

The range of frequencies used for each channel vary depending on the carrier's particular implementation. Each channel occupies a different portion of the frequency spectrum, as shown in the figure, which illustrates a possible implementation of ADSL. The baseband voice channel is split off from the data channels to guarantee phone services in case the data channel fails. Data transmission rates in the upstream direction range from 128 kilobits per second (Kbps) to 1.54 megabits per second (Mbps), and those in the downstream direction range from 384 Kbps to 7.1 Mbps, depending on the length of the local loop—the distance from the customer premises to the telco's (CO) central office—and the telephone cable's wire gauge. The longer the distance from the customer premises to the CO, the slower the ADSL speed that can be achieved (this feature is why ADSL is referred to as a "best effort" service). ADSL speeds start to drop significantly when the subscriber is beyond 10,000 feet from the CO due to interference, attenuation, and crosstalk, and ADSL becomes almost totally ineffectual beyond 18,000 feet. ADSL speeds also vary depending on the AWG gauge of the twisted-pair telephone wires in the subscriber's local loop and residence, with 24 gauge wire providing better performance than 26 gauge.

In a typical ADSL implementation, an ADSL modem (technically called an ADSL Transmission Unit-Remote, or ATU-R) is used to connect a subscriber's computer or network to a standard analog POTS phone line. The ADSL modem contains a POTS splitter chip that splits the bandwidth of the phone line into a voice and a data channel. The data channel is then split, using a channel separator chip, into a separate upstream and downstream channel, with the downstream channel having the larger portion of allocated bandwidth. The voice band typically uses frequencies from 0 to 3.4 kilohertz (kHz), while the data channels use higher frequencies anywhere from above 26 kHz to beyond 1100 kHz, depending on the carrier's implementation. Carrying capacity depends on the wire's thickness and other line conditions.

At the other end of the subscriber's local loop is another ADSL modem (properly called an ADSL Transmission Unit-Central Office or ATU-C) at the telco's CO. The telco's modem separates the voice signal from the data stream using a splitter and routes voice calls through the POTS system of telco switches, while the data is routed to a Digital Subscriber Line Access Multiplexer (DSLAM) unit. The DSLAM unit combines multiple ADSL lines into a single pipe for transmission over the carrier's fiber-optic Asynchronous Transfer Mode (ATM) backbone network to the Internet or to other DSL provider networks. This process is known as ATM over ADSL.

ADSL can employ several different modulation systems for encoding the data channels:

- Carrierless amplitude/phase (CAP)
- Discrete multitone (DMT)
- Discrete wavelet multitone (DWMT)

asymmetric multiprocessing (AMP)

A processing architecture in which processes are specifically assigned to different processors.

Overview

When asymmetric multiprocessing (AMP) is used on a multiprocessor computer (a computer with more than one CPU), each processor is assigned specific tasks to perform. For example, one processor might be dedicated to managing input/output (I/O) requests, another to executing network requests, another to running a user application, and so on.

AMP contrasts with symmetric multiprocessing (SMP), in which the operating system evenly distributes the application load across multiple processors. In SMP, individual processes are not mapped to specific

processors but instead are assigned to available processors by the operating system.

Notes

Microsoft Windows 2000 supports SMP but not AMP.

async

Short for asynchronous transmission, a form of data transmission in which the transmitting and receiving stations do not explicitly coordinate their transmissions with each other.

Asynchronous Transfer Mode (ATM)

A high-speed, broadband transmission data communication technology based on packet switching and multiplexing technologies, and used by telcos, long distance carriers, and campus-wide backbone networks to carry integrated data, voice, and video information.

Overview

Asynchronous Transfer Mode (ATM) technology originated in the late 1970s and early 1980s through research into broadband Integrated Services Digital Network (ISDN) (B-ISDN). Like Internet Protocol (IP), ATM is basically a packet-switching technology, but unlike IP with its variable-length packets, ATM uses fixed-size packets called "cells." The fixed size of an ATM cell makes ATM traffic simple and predictable, and makes it possible for ATM to operate at high speeds.

ATM works primarily at Layer 2 of the Open Systems Interconnection (OSI) reference model and so its operation is independent of the Physical Layer (PHY) transport used. The speeds at which ATM operate depend on the transmission medias being used. The various speeds available include:

- 1.544 megabits per second (Mbps) to 25 Mbps over unshielded twisted-pair (UTP) Category 5 (Cat5) cabling, also known as "ATM to the desktop." This early ATM initiative was derailed by the rapid

advances in Fast Ethernet, which won out over ATM because of its simplicity and lower cost.

- 155 Mbps (OC-3) over either UTP or fiber-optic cabling, used primarily for connecting wiring closets to backbone networks.
- 622 Mbps (OC-12), 2.4 Gbps (OC-48), and 4.8 Gbps (OC-96) over fiber-optic cabling only, used exclusively for ATM core (backbone) networks and Synchronous Optical Network/Synchronous Digital Hierarchy (SONET/SDH) as PHY layer transport.

The *asynchronous* in *ATM* means ATM devices do not send and receive information at fixed speeds or using a timer but instead negotiate transmission speeds based on hardware and information flow reliability. The *transfer mode* in *ATM* refers to the fixed-size cell structure used for packaging information. This cell-based transmission is in contrast to typical local area network (LAN) variable-length packet mechanisms, which means that ATM connections are predictable and can be managed so that no single data type or connection can monopolize the transmission path. As a result, ATM is suitable for transmitting all types of traffic from “bursty” data transmissions to real-time and packaged voice and video playback.

Different “classes of service” are used to accommodate transmission of different traffic types in optimal ways, and ATM optimizes traffic flow performance through these various classes of service, which can be allocated on a per-connection basis by using ATM’s Quality of Service (QoS) settings. In this fashion, ATM is different from frame relay, which is essentially a classless service. Note that not all carriers or ATM switching gear support all of these service categories.

The six service categories currently defined for ATM defined by the ATM Forum are

- **Constant Bit Rate (CBR):** This level is suitable for applications that require a relatively static amount of bandwidth over the duration of a connection. An example might be network control traffic.

- **Real-time Variable Bit Rate (rt-VBR or VBR-RT):** This level is suitable for real-time applications such as video and voice that are sensitive to delay and use large amounts of bandwidth.
- **Non-real-time Variable Bit Rate (nrt-VBR or VBR-NRT):** This level is suitable for bursty traffic that is not real-time in nature. An example might be data acquisition in experiments or playback of canned video presentations.
- **Unspecified Bit Rate (UBR):** This level is suitable for traffic that is not delay sensitive and non-real-time. Examples might include e-mail and file transfers.
- **Available Bit Rate (ABR):** This level includes a flow-control mechanism and is therefore suitable for non-real-time traffic where the transmission characteristics are subject to change over the life of the connection. An example might be file transfers over a noisy link.
- **Guaranteed Frame Rate (GFR):** This level allows additional bandwidth to be allocated dynamically when needed.

ATM also includes a mechanism for allocating bandwidth dynamically; that is, bandwidth is allocated only in required amounts and the required direction. As a result, when an ATM link is idle, it utilizes no bandwidth, which can result in considerable cost savings depending on the needs of your network. ATM networks use bandwidth at maximum efficiency, while maintaining guaranteed QoS for users and applications that require it.

The evolution of ATM has been guided since 1991 in large measure by the efforts of the ATM Forum. ATM is also based on a group of international signaling and interface standards defined by the International Telecommunication Union (ITU). These standards include the user network interface (UNI) standards that specify how users connect to ATM networks, and the broadband intercarrier interface (B-ICI) and public network-to-network interface (P-NNI) standards for establishing connectivity between different ATM networks.

Uses

ATM was originally envisioned as an end-to-end networking architecture that would supersede Ethernet and Token Ring in enterprise LANs because of its built-in support for QoS. Initial deployments included backbones for enterprise LANs with the vision to carry ATM directly to the desktop, but the rapid evolution, simplicity, and lower cost of Fast Ethernet and, later, Gigabit Ethernet (GbE) have prevented ATM from fulfilling its original vision. Few enterprises deploy new ATM backbones today, and the emergence of 10 Gigabit Ethernet (10 GbE) makes this even more unlikely in the future.

If ATM in the backbone is declining in the enterprise, ATM for WAN access remains relatively strong. GbE backbone switches with core ATM ports can be used to connect enterprise networks to carrier's ATM networks for remote access to branch offices and subsidiaries. Alternatively, an Integrated Access Device (IAD) aggregates network traffic at the customer premises into a single ATM WAN pipe for connection to the carrier.

ATM has been widely adopted in the communications networks of telecommunication carriers (telcos). ATM metropolitan area networks (MANs) are widespread, and ATM is viewed as the de facto technology for long distance fiber-optic communication lines stretching thousands of kilometers across continents.

ATM hardware spans the whole range of networking infrastructure, including ATM backbone switches and edge switches, ATM multiplexers, ATM remote access devices, and ATM network interface cards.

Architecture

ATM uses fixed-size 53-byte cells. Each cell contains 48 bytes of payload (data) and 5 bytes of control and routing information in the header. The 5-byte header provides addressing information for switching the packet to its destination and can be implemented in one of two formats: User to Network Interface (UNI) or Network Node Interface (NNI).

The 48-byte payload section carries the actual information, which can be data, voice, or video. The payload is properly called the user information field. The reason for choosing 48 bytes as the payload size is to

compromise between the optimal cell sizes for carrying voice information (32 bytes) and data information (64 bytes).

ATM uses a layered architecture for its protocol stack, similar in some respects to the lower portions of the OSI model. There are three main layers in the ATM architecture:

- **ATM Adaptation Layer (AAL):** This is the top layer in ATM and is responsible for guaranteeing service characteristics of transmission and for building different types of data into the 48-byte cell payload. It is called the Adaptation Layer because it adapts the ATM Layer beneath it to the particular services that will be using it. The ATM Adaptation Layer consists of two sublayers, the Convergence Sublayer (CS) and the Segmentation and Reassembly (SAR) sublayer. The ATM Adaptation Layer supports five different AAL protocols from AAL 1 through AAL 5, with the last one being the most widely used. The ATM Adaptation Layer is equivalent to the OSI model's Data Link Layer.
- **ATM Layer:** This middle layer takes the payload formed by the ATM Adaptation Layer and adds the 5-byte header information and routes the packet to its destination.
- **Physical Layer:** This bottom layer defines the electrical characteristics of the network interface and media over which the ATM cell is transmitted and converts the ATM cell into electrical signals. In other words the Physical Layer "puts the bits onto the wire." ATM supports a variety of different PHY level transports, including SONET, SDH, DS3/E3, Fiber Distributed Data Interface (FDDI), and Fibre Channel. The ATM Layer and Physical Layer are together equivalent to the OSI model's Physical layer.

ATM supports a variety of address formats. Public ATM networks implemented by telecommunications carriers use the same 19-byte E.164 addresses used by Narrow-band ISDN. Private ATM networks can use three different address formats: Network Service Access Point (NSAP) encapsulated E.164, Data Country Code (DCC), and International Code Designator (ICD).

ATM is generally deployed in a star topology with the ATM switch at the center acting as a concentrator. The advantages of this topology are that troubleshooting is simplified and the network can easily be reconfigured if required. ATM switches can provide bandwidth on demand, and additional connections can be formed with the switch when more bandwidth needs to be added.

ATM is a connection-oriented technology that supports both point-to-point and point-to-multipoint connections, but multipoint connections require multicasting (ATM does not support broadcasts). ATM requires the establishment of a specific network path between two points before data can be transported between them. This path is negotiated by the transmitting station, which specifies the type of connection (service classes discussed above), speed (bandwidth) required, and other attributes.

The paths with which ATM connects end stations are called virtual channels (VCs). Virtual channels consist of one or more physical ATM links connected in a series for transmitting data between remote stations. A VC exists only while data is being transmitted on it, and all cells in a given ATM transmission follow the same VC to ensure reliable data transmission. A virtual path (VP) is a collection of VCs having the same source and destination points that can be used to pool traffic being transmitted to a given destination. The header of an ATM cell contains routing information that defines the VC being used for the connection. This routing information is called the Virtual Path Identifier/Virtual Channel Identifier (VPI/VCI).

VCs and VPs are the basic building blocks of ATM networks and provide end-to-end connections with well-defined end points and traffic routes. VCs may be of two types: permanent virtual circuits (PVCs) and switched virtual circuits (SVCs). ATM can work with either PVCs or SVCs, depending on your wide area network (WAN) traffic needs. PVCs are more commonly used by ATM service provider networks but are less efficient with respect to bandwidth costs.

Typically a subscriber needing an ATM WAN link for their company leases a T1 or T3 line to connect their customer premises equipment (CPE) to the

telecommunication carrier's ATM network, but frame relay or SONET can also be used to connect a site to an ATM network. The kind of CPE needed varies with the access method employed—for example, Channel Service Unit (CSU) for T1 line, frame relay access device (FRAD) or router for frame relay, and so on. Large corporate networks using an ATM backbone might use a switch-to-switch connection to the carrier's network instead of CPE.

Advantages and Disadvantages

ATM's two main benefits are its high transmission speeds and its flexible bandwidth-on-demand capability. ATM has the following advantages over competing high-speed networking technologies:

- High-speed, fast-switched integrated data, voice, and video communication that is not bound by the physical or architectural design constraints of traditional LAN networking technologies.
- A standards-based solution formalized by the ITU that allows ATM to easily replace existing telephony network infrastructures. ATM provides a global telephony standard, and more than 70 percent of U.S. telcos have migrated their internal networks to ATM.
- A fixed-length cell-based transmission that is suitable for transport of real-time traffic such as voice and video and which allows high-speed bulk encryption mechanisms to be implemented easily and in an affordable way.
- Interoperability with standard LAN/WAN technologies. ATM networks can be interconnected with Ethernet and token ring LANs using LAN emulation (LANE) services to provide Transmission Control Protocol/Internet Protocol (TCP/IP) over ATM.
- Built-in support for QoS that enables a single ATM network connection to reliably carry voice, data, and video simultaneously and manage bandwidth on a per connection basis depending on the priority of the service required. By assigning a bandwidth profile to an ATM connection, the performance of the connection can be guaranteed.

- A connection-oriented architecture that makes it resistant to the kind of denial of service (DoS) attacks for which Internet Protocol (IP) networks are famous. ATM is a more secure solution than IP for the trust boundary where WAN links are found in enterprise networks.

On the other hand, ATM has some significant disadvantages that have hindered its widespread adoption in enterprise networks:

- ATM switching equipment is more expensive than gear for competing technologies such as GbE.
- ATM is more complex in its architecture and operation than competing technologies. By contrast, GbE is an easy step upwards from Fast Ethernet.
- The ATM vision of integrated voice/video/data throughout the enterprise (a.k.a. “convergence”) is not driven by market pressure, so in some ways ATM remains “a solution in search of a problem.”
- Support for ATM in the WAN market has also been hindered by the fact that most carriers have not yet deployed switched virtual circuits (SVCs) and instead continue to rely upon static permanent virtual circuits (PVCs), which are less flexible and provide a fixed amount of bandwidth at a relatively high cost. Moving to SVCs would reduce costs for customers by enabling bandwidth-on-demand, but most carriers are reluctant to make the capital outlay for upgrading their switching equipment if the end result is to reduce immediate revenue by lowering costs.

Marketplace

Some of the larger carriers offering ATM services for the WAN/MAN environment include AT&T, Bell Atlantic/GTE, MCI WorldCom/UUNET, Qwest/US WEST, and Sprint. These carriers all offer high-performance services with minimal transit delays, and some of them offer ATM-to-frame relay services as an option as well, allowing multiple remote sites connected by frame relay to have their links aggregated into a single fat ATM pipe.

Marconi is the leading vendor of ATM switching equipment, with a 30 percent share of the market in 1999.

Cisco Systems came second with a 25 percent share and has lately been focusing its research and development on packet-over-ATM, the next generation of ATM technologies. Other switch vendors offering ATM modules include Nortel Communications and Enterasys.

The region of the world that currently has the highest investment in ATM technologies is the Asia/Pacific region, where leased lines are expensive and ATM is seen as an affordable solution for the needs of the corporate WAN. By contrast, in North America the cost of leased lines is lower, making carrier-based ATM services unattractive and tending to drive large companies to running ATM over their own private circuits.

Prospects

ATM was once hailed as a revolutionary technology superior to Ethernet and essential for enterprises seeking “convergence,” that is, the transmission of voice, video, and data over network backbones. However, its growth in deployment has been hindered by the high cost of ATM equipment and the complexity of implementing and managing it. Meanwhile, bandwidth supported by Ethernet has continued to grow, with the result that few enterprises are contemplating the deployment of new ATM backbones, with most favoring GbE instead. The early dream of corporate ATM networks stretching from the server room to the desktop has all but vanished.

ATM’s largest installed base remains in telcos, and ATM or SONET/ATM remains the standard high-speed networking solution for these companies. Most MANs deployed by carriers are still ATM, and attempts by GbE to encroach on this territory have been hindered by the still nascent QoS features currently available for Ethernet. With the advent of 10 GbE, however, the picture may change as new carriers such as Yipes (www.yipes.com) move into the MAN space offering enterprises end-to-end Ethernet across the WAN. The long-distance carrier market, however, is destined to remain purely ATM for the foreseeable future, and most Incumbent Local Exchange Carriers (ILECs) have invested too heavily in ATM technologies for them to easily make the switch to 10 GbE.

ATM has received a boost in the last couple of years through increasing deployment of business and residential

Digital Subscriber Line (DSL) for providing Internet access to the customer premises. Many local telcos aggregate DSL traffic from subscribers into ATM pipes for transport to their backbone ATM carriers. However, DSL is itself facing stiff competition from cable modem providers, and which technology will win out is unclear.

The greatest threat to ATM's survival in the industry is the development of QoS mechanisms for IP traffic. Standards such as Multiprotocol Label Switching (MPLS) and Differentiated Services (DiffServ) have shown some initial promise but cannot compete at this point with ATM, which is still king of the QoS hill. Solutions such as 10 GbE may succeed by simply throwing bandwidth at the problem, but ultimately incorporating QoS into IP is essential if the vision of enterprise convergence is to be attained.

Notes

A number of different approaches are available for building IP internetworks with ATM backbones. These include

- **Classical IP (CIP):** Based on RFC 1577, this supports only the IP protocol and requires a special Address Resolution Protocol (ARP) Server to handle the broadcasts required to support IP (ATM does not support broadcasts because it is connection-oriented in nature). When CIP is deployed over ATM WAN connections using permanent virtual circuits, it is called CIP over PVC.
- **LANE (LAN Emulation):** Lets you build bridged virtual LAN segments for enabling an ATM network to emulate an Ethernet or Token Ring network. LANE is an early solution developed by the ATM Forum.
- **MPOA (Multiprotocol Over ATM):** Provides a virtual router for creating virtual IP subnets over ATM. MPOA is a more recent initiative of the ATM Forum.
- **MPLA (Multiprotocol Label Switching):** A technology developed by the Internet Engineering Task Force (IETF) for a label-based routing system for carrying IP and other traffic over ATM.

For more information on each of these technologies, see their respective articles elsewhere in this book.

ATM can also be used as the underlying technology for FDDI.

Microsoft Windows 2000, Windows XP, and Windows .NET Server support direct connectivity to ATM networks with up to four ATM adapters in a single computer.

asynchronous transmission

A form of data transmission in which the transmitting and receiving stations do not explicitly coordinate their transmissions with each other.

Overview

Asynchronous transmission (async) is used in serial transmission for modems and other telecommunication devices. Data is transmitted as streams of bytes terminated by start and stop bits, and the transmitting station can wait an arbitrary period of time between transmissions. This contrasts with synchronous transmission (sync), in which a timing or clocking mechanism is used to ensure a steady flow of data between the devices.

In asynchronous communication, only about 80 percent of the transmitted bits actually contain data, while the other 20 percent contain signaling information in the form of start and stop bits. Each data frame starts with a start bit and ends with a stop bit, with data bits in between. When the receiving station receives a start bit, it knows that pure data will follow. When it receives a stop bit, it knows the data frame has ended and waits for the next one.

Asynchronous transmission is essentially character-based with additional bits between characters to enable synchronization and error correction. An optional parity bit for error checking can be located immediately before the stop bit in each frame. With parity correction, an 8-bit character requires 3 bits of control information (start, stop, and parity bits), which means an actual overhead of 3/8, or 38 percent.

Asynchronous communication is not synchronized by a timer mechanism or clock, and asynchronous devices are not bound to send or receive information at an exact transmission rate. Instead, the sender and receiver negotiate transmission speeds based on hardware limitations and the need to maintain a reliable flow of information. Asynchronous transmission is mainly suitable for low-speed transmission, but speeds can also be increased by using data compression.

Notes

Cisco routers may use any of four different kinds of async ports:

- RJ-45 jack for standard console and aux ports.
- DB-25 serial connector for Cisco 4000 series routers.
- DB-60 connector, switchable from sync to async using Internetwork Operating System (IOS).
- 68-pin Small Computer System Interface (SCSI) II connector for providing eight serial ports (acts as a serial port concentrator) and typically found on access servers.

ATM Adaptation Layer (AAL)

An Asynchronous Transfer Mode (ATM) protocol that performs the functions of the Open Systems Interconnection (OSI) model's Data Link layer.

Overview

The function of the ATM Adaptation Layer (AAL) is to adapt the ATM Layer protocol to high-level networking protocols above it. The AAL consists of two sublayers:

- **Convergence Sublayer (CS):** Top sublayer, responsible for performing functions relating to the class of service specified for the traffic being transported over ATM.
- **Segmentation And Reassembly (SAR):** Bottom sublayer, responsible for breaking up high-level data streams into 48-byte segments for packaging into ATM cells. If there's insufficient data to form a cell, SAR pads the cell to make a full cell.

The ATM Adaptation Layer supports five different AAL protocols from AAL 1 through AAL 5, with the last one being the most widely used.

ATM Forum

An international not-for-profit organization dedicated to promoting the deployment of Asynchronous Transfer Mode (ATM) products and services.

Overview

The ATM Forum was founded in 1991 by a consortium of four companies (Cisco Systems, Northern Telecom [now Nortel Communications], Sprint Corporation, and Net/Adaptive). The ATM Forum's goal is to help steer the course of the development of ATM standards and technologies with the cooperation of over 600 industry partners (the Forum is itself not a standards body but instead develops specifications and submits them to the International Telecommunication Union [ITU]).

The ATM Forum works by committees, some of which include

- **The Technical Committee:** Works with other standards bodies such as the ITU to develop and evolve ATM standards and ensure interoperability between

them. A number of different working groups are under this committee's umbrella.

- **Market Awareness Committees:** Three of these committees cover the North America, Europe, and Asia/Pacific regions.
- **The User Committee:** This consists of ATM users and allows them to provide input to the other committees based on their real-world experience of using ATM.

The ATM Forum also has an Ambassador Program for providing speakers knowledgeable about ATM for conferences and other events. The ATM Forum also has a newsletter called "53 Bytes," which helps keep people informed of developments in the ATM field.

ATM over SONET

Also called ATM/SONET, a data transmission technology in which Asynchronous Transfer Mode (ATM) cells are transmitted over Synchronous Optical Network (SONET) circuits.

Overview

ATM over SONET is a technology used by telecommunications carriers when individual circuits have to carry multiple different kinds of traffic such as voice, video, Internet Protocol (IP), and so on. Implementing ATM over SONET adds an additional 5 bytes of overhead to 53-byte ATM cells, so this is done only when necessary. If a SONET circuit carries only one type of traffic—such as IP packets or circuit-switched voice—the ATM layer is not required, thus saving the additional overhead.

ATM over SONET can be implemented either with or without Automatic Protection Switching (APS), the traditional SONET ring-based redundancy technology.

attenuation

The loss of signal strength over long distances when signals travel along cabling.

Overview

Attenuation values for actual cables are measured in units of decibels (dB)—a standard measurement value used in communication for expressing the ratio of two values of voltage, power, or some other signal-related quantity. For example, a drop of 3 dB corresponds to a decrease in signal strength of 50 percent or 2:1, while a drop of 6 dB corresponds to a decrease of 75 percent or 4:1. Attenuation values for cabling media are expressed in units of decibels per 1000 feet, which express the amount of attenuation in decibels for a standard 1000-foot (305-meter) length of cabling composed of that medium.

Attenuation. *Attenuation of analog and digital signals.*

Copper cabling has much greater attenuation than fiber-optic cabling, which makes copper suitable only for relatively short cable runs. Typical attenuation values for

copper Category 5 (Cat5) cabling vary with frequency and are shown in the following table. Attenuation for lower-grade cable is slightly higher.

Attenuation Values for Copper Cat5 Cabling

Signal Frequency	Attenuation
4 megahertz (MHz)	13 dB/1000 feet
10 MHz	20 dB/1000 feet
20 MHz	28 dB/1000 feet
100 MHz	67 dB/1000 feet

Notes

Attenuation is caused by signal absorption, connector loss, and coupling loss. To minimize attenuation, use high-grade cabling such as enhanced category 5 (Cat5e) cabling. Also try to minimize the number of connector devices or couplers, ensuring that these are high-grade components as well. When a signal attenuates a large amount, the receiving device might not be able to detect it or might misinterpret it, therefore causing errors.

attenuation to crosstalk ratio (ACR)

The ratio of the received strength of a signal on a pair of wires to the amount of crosstalk between the wires.

Overview

The attenuation to crosstalk ratio (ACR) is calculated as the difference between the attenuation value and the near-end crosstalk value at a specific frequency. This is because both attenuation and crosstalk are usually expressed in units of decibels for cabling media. The decibel scale is logarithmic in nature, which means that a difference in decibel values corresponds to a ratio of actual signal voltage or power levels.

The higher the ACR for a given cable, the less chance of signal errors. For copper Category 5 (Cat5) cabling, the ACR value is typically about 10 decibels (dB), at a frequency up to about 100 megahertz (MHz). This value decreases slightly with increasing frequency until crosstalk and attenuation values converge, at which point transmission becomes error prone and the cabling ineffective for communication.

attrib command

A Microsoft Windows command that can be used to display and modify the attributes of files and directories.

Overview

You can use the attrib command to display and modify the archive, system, hidden, and read-only attributes that can be assigned to files and directories. For example, if you need to manually modify the boot.ini file on a machine running Windows 2000, you can use the attrib command to remove its read-only, hidden, and system attributes.

Examples

```
attrib -r -h -s boot.ini
```

This removes the read-only, hidden, and system attributes from the boot.ini file, allowing you to edit the file manually.

attribute (file system)

A type of marker that can be set or cleared for files on a file system such as NTFS file system (NTFS).

Overview

On NTFS, attribute markers determine whether a file is

- Read-only, meaning that it cannot be modified
- Hidden, meaning that the file will not appear when its parent directory is listed at the command line
- System, meaning that the file is a critical operating system file and should not be moved or modified
- Archived, meaning that the file has been backed up
- Encrypted using Microsoft Corporation's Encrypting File System (EFS) (Windows 2000, Windows XP, and Windows .NET Server only)
- Compressed (Windows 2000, Windows XP, and Windows .NET Server only)

To view or modify the attributes of a file, open the file's property sheet and check or clear the appropriate check box.

Notes

The term *attribute* can also refer to other more granular file system information, such as time stamps, file size, or link counts.

attribute (Active Directory)

A property of an object in Active Directory directory service.

Overview

Attributes are information relating to objects stored in Active Directory. For example, a user class object is composed of attributes, such as a First Name attribute for a user account object.

Attributes define the actual characteristics of objects in Active Directory. Every class of objects has its own defining set of attributes. Different objects within this class are distinguished by the values of their attributes. Some attributes, such as the First Name attribute for a user account object, must have a value assigned to them when they are created. Other attributes, such as Phone Number, can optionally be left unvalued.

Each attribute in Active Directory is defined only once and can be used for many different object classes. All objects of the same type have the same set of attributes. Different objects of the same type are distinguished by different attribute values. It is therefore the values of the attributes of a particular object that make that object unique in Active Directory.

Attributes are defined in a special portion of Active Directory. An attribute definition includes

- The syntax (type of information) of the attribute, such as integer, date, or string
- Whether the attribute is single-valued or multivalued

Each syntax type is specified by an object identifier, which is a globally unique identifier (GUID) issued by the International Organization for Standardization (ISO). The allowable syntax types for attributes of objects in Active Directory are shown in the following table.

Allowable Syntax Types for Object Attributes

<i>Syntax</i>	<i>Object Identifier</i>	<i>Description</i>
Undefined	2.5.5.0	Not a legal syntax
Distinguished name	2.5.5.1	The fully qualified name of an object in the directory
Object identifier	2.5.5.2	Identifies an object
Case-sensitive string	2.5.5.3	Differentiates upper-case and lowercase
Case-insensitive string	2.5.5.4	Does not differentiate uppercase and lowercase
Print case string	2.5.5.5	Printable string
Numeric string	2.5.5.6	A sequence of digits
OR name	2.5.5.7	An x400 e-mail address
Boolean	2.5.5.8	TRUE or FALSE
Integer	2.5.5.9	A 32-bit number
Octet string	2.5.5.10	A string of bytes
Time	2.5.5.11	The number of seconds elapsed since 1/1/1970
Unicode	2.5.5.12	Wide string
Address	2.5.5.13	Internal
Distname-address	2.5.5.14	Internal
NT security descriptor	2.5.5.15 66	Microsoft Windows NT Security Descriptor
Large integer	2.5.5.16	A 64-bit number
Security identifier (SID)	2.5.5.17 4	SID

ATU-C

Stands for Asymmetric Digital Subscriber Line (ADSL) Transceiver Unit, Central Office end, an ADSL modem that terminates a subscriber's ADSL connection at the ADSL provider's Central Office (CO).

ATU-R

Stands for Asymmetric Digital Subscriber Line (ADSL) Transceiver Unit, remote terminal end, an

auditing

The process of tracking and monitoring actions performed on servers or networks for security purposes.

Overview

Auditing is an important component of a general security policy for a corporate network. Auditing can be used to detect attempts at unauthorized access to network resources and to track the usage of shared resources. Auditing creates a record of which files have been accessed, who has logged on to the network, who has attempted to use a shared resource, and so on. Specifically, auditing records information in the security log about

- What action was performed
- Who performed the action
- When the action occurred
- Whether the action succeeded or failed

Notes

Microsoft Windows 2000, Windows XP, and Windows .NET Server record two kinds of auditing information in the security log:

- **Success audits:** Symbolized by keys and usually used to track resource usage for capacity and resource planning
- **Failure audits:** Symbolized by padlocks and usually used to monitor network resources for unauthorized access attempts

See Also: *Audit policy, event, security log*

Audit policy

A policy established on a Microsoft Windows 2000 or Windows .NET Server domain that specifies the kinds of security-related events that will be recorded in the security log.

Overview

The following table indicates the kinds of events that can be audited in Windows 2000, Windows XP, and Windows .NET Server.

Events That Can Be Audited

<i>Type of Event</i>	<i>Description</i>
Logon and logoff	Users logging on and off and forming network connections
File and object access	Users accessing a file, folder, or printer on a network
Use of user rights	A right has been exercised—for example, backing up files and directories
User and group management	An account has been modified, created, or deleted
Security policy changes	A change has been made to an Audit policy, a trust relationship, or user rights
Restart, shutdown, and system	The system has been shut down or restarted, or system security has changed
Process tracking	A process has been started or stopped, or some related activity has occurred

Notes

Be careful when enabling auditing for File And Object Access or Process Tracking because logging these events can generate a large amount of overhead on your system, especially when auditing for successes. To audit access to a file, folder, or printer, first enable File And Object Access auditing in your Audit policy, and then access the Security tab on the object's property sheet.

AUI connector

Stands for Attachment Unit Interface connector, a standard 15-pin connector device for thicknet.

Overview

The AUI connector on the free end of a 10Base5 drop cable attaches to the DB15 connector on the network interface card (NIC). The NIC has an AUI port connector for connecting the drop cable. The other end of the

drop cable typically connects to a transceiver. The transceiver is then joined to the thicknet cabling using a vampire tap that pierces the cable jacket and insulation to make a connection.

Authenticated Users group

A built-in group in Microsoft Windows 2000, Windows XP, and Windows .NET Server for controlling access to resources.

Overview

The Authenticated Users group is similar to the built-in Everyone group, except that anonymous logon users are never members of the Authenticated Users group. The built-in security identifier (SID) for this group is S-1-5-11.

The Authenticated Users group can be used to provide additional security when running Microsoft Internet Information Services (IIS) because the anonymous user account has the ability to enumerate share names and list domain usernames. Using the Authenticated Users group provides an additional layer of security and is one way to restrict access to objects in the file system.

You should generally use the Authenticated Users group instead of the Everyone group if you want to carefully control anonymous access to your network resources.

Authentication Header (AH)

A protocol in the IPSec suite of protocols that handles authentication of Internet Protocol (IP) traffic.

Overview

The Authentication Header (AH) header immediately follows the IP header of an IP packet and includes the following fields:

- **Next Header (1 byte):** This field indicates which protocol (Transmission Control Protocol [TCP] or User Datagram Protocol [UDP]) is used in the payload immediately following the AH header.
- **Payload Length (1 byte):** This field indicates the length of the payload following the AH header.

- **Reserved Area (2 bytes):** Not currently used.
- **Security Parameters Index or SPI (4 bytes):** Specifies which security protocols are being used for the transmission of the packet.
- **Sequence Number (4 bytes):** Indicates the position of the packet in the sequence of packets having the same SPI.
- **Authentication Data (variable):** Contains the digital signature for the packet.

Notes

AH usually uses MD5 as its encryption algorithm, but other more secure encryption algorithms can also be used.

See Also: *IPsec*

authentication protocol

Any protocol used for validating the identity of a user to determine whether to grant the user access to resources on a network.

Overview

Authentication protocols can be classified according to how the credentials are passed over the network. Some common kinds of authentication protocols include

- **Anonymous access:** This method is supported by Microsoft Internet Information Services (IIS) and allows anonymous users on the Internet access to Web content on your server.
- **Basic authentication:** This method transmits passwords as clear text and is often used in Unix networks and for File Transfer Protocol (FTP) services. It is also supported by IIS.
- **Digest authentication:** This method hashes (digests) the user's password before transmitting it, making it more secure than Basic authentication. Digest authentication is part of the Hypertext Transfer Protocol (HTTP) 1.1 protocol and is also supported by IIS.
- **Windows NT Challenge/Response:** This is the standard secure authentication method for Windows NT domains. In IIS this protocol is referred to as Integrated Windows authentication. Also called Windows NT Lan Manager or NTLM.

- **Kerberos v5:** This is the standard authentication security protocol for Windows 2000 and Windows .NET Server domains.
- **X.509 Client Certificate authentication:** This is used in conjunction with Secure Sockets Layer (SSL) and digital certificates and is also supported by IIS.

Notes

On a Microsoft Windows NT, Windows 2000, or Windows .NET Server network, authentication can be handled in one of two ways:

- When logging on to a member server or stand-alone workstation, authentication is performed by the member server or workstation itself using its local Security Accounts Manager (SAM) database.
- When logging on to a domain, authentication is performed by a domain controller on the network.

authentication provider

In Internet Connection Services for Microsoft Remote Access Service (RAS), a database for providing AAA (authentication, access, and accounting) information for the users in a given realm.

Overview

An authentication provider is a server that is used by Internet Authentication Service (IAS) to map a Remote Authentication Dial-In User Service (RADIUS) authentication request to a database containing user credentials. The authentication provider can verify or deny whether the individual exists in the database and return this information to the IAS server.

Choices for authentication providers are

- A Microsoft Windows NT, Windows 2000, or Windows .NET Server domain controller
- A Local Users file on the IAS server
- An open database connectivity (ODBC)–compliant database

- A Microsoft Commercial Internet System (MCIS) membership database

Authenticode

A Microsoft security technology that certifies the identity of the publisher of software to ensure the software has not been tampered with.

Overview

To use Authenticode, an Internet software publisher first obtains a digital certificate from a certificate authority (CA). They then use Authenticode signing tools to digitally sign the application.

When a user tries to download the application from the Internet, client-side Authenticode software in Microsoft Windows displays the publisher's certificate information to help the user make a more informed decision about whether to install the software on his or her machine.

Authenticode can be used to sign Microsoft ActiveX controls, .cab files, Java applets, or any other executable files.

Authorized Academic Training Provider (AATP)

A Microsoft training program offered to accredited academic institutions.

Overview

An Authorized Academic Training Provider (AATP) is an educational institution approved for delivery of training on Microsoft platforms and applications. AATPs can include secondary schools, vocational schools, community colleges, and universities. Microsoft Corporation provides participating institutions with tools to facilitate courseware delivery that prepares students for Microsoft Certified Professional (MCP) certifications. This enables schools to serve their communities by educating future employees to fill demands for technically certified computer professionals.

There's no fee for joining the AATP program. Some of the benefits of joining the program include the following:

- A 100-user software license received upon purchase of a Microsoft product—provided the product is the subject of a course being taught that uses a Microsoft Official Curriculum or Microsoft Approved Study Guides. Note that these licenses are for student and instructor use in the classroom only.
- Special academic pricing on Microsoft Official Curriculum and Microsoft Approved Study Guides.
- Online course outlines, evaluation tools, curriculum materials, certification fact sheets, and preparatory exams.
- Access to the private AATP Internet site.

Notes

An organization or institution cannot participate simultaneously in both the AATP and Certified Technical Education Center (CTEC) programs.

For More Information

auto-application

An application that can be automatically started on the user's computer by Microsoft Connection Manager (CM) after a connection is established.

Overview

Auto-applications automatically launch and close upon the start and end of a connection. This lets administrators configure services to trigger when users open their e-mail or Web browser.

You can specify auto-applications using a wizard that allows you to specify the name of the application, command-line switches or parameters, and other information.

An auto-application must be a complete program file. It cannot require other files to work, and it cannot be a self-extracting executable.

AutoComplete

A feature of Microsoft Internet Explorer that attempts to complete a partial Uniform Resource Locator (URL) entered into the browser's Address field.

Overview

When you begin to enter a URL, the AutoComplete function checks the browser's history folder for any URLs that match your partial URL and displays the closest match to what you have entered. This saves users from having to retype long URLs when attempting to revisit a site.

AutoComplete can be viewed as both an accessibility feature and a way to avoid time-wasting mistakes. If the URL that AutoComplete suggests for you is incorrect, just keep typing the URL you want.

AutoComplete is based on the same IntelliSense technology that is implemented in certain features of Microsoft Office, such as the AutoFill feature in Microsoft Excel.

Notes

If you clear your history folder, AutoComplete will not be able to function because it uses URLs stored in that folder. The longer you leave your history folder unemptied, the larger its contents become and the more effectively AutoComplete operates.

autodial

A feature of remote access in Microsoft Windows 2000, Windows NT, Windows XP, and Windows .NET Server that maps network resources to phonebook entries.

Overview

When a user or application tries to access a network resource, autodial automatically tries to establish a connection to the resource. To configure autodial in Windows 2000, go to Control Panel in My Computer, and then open Network And Dial-up Connections. Choose Dial-Up Preferences from the Advanced menu. On the Autodial tab, select the check box next to the location where you want to enable autodial, and then click OK. To configure AutoDial in Windows NT, use the User Preferences dialog box for your phonebook entry.

Notes

Certain actions will not trigger autodial. These include

- Pinging an Internet Protocol (IP) address. (Pinging a fully qualified domain name, however, will cause autodial to engage.)
- Using both a dial-up and a local area network (LAN) connection. (AutoDial engages only after an attempt to connect over the LAN has failed.)

automatic logon

A logon process whereby the user gains access to the network through user credentials previously stored in the registry.

Overview

Automatic logon can be enabled on a machine running Microsoft Windows NT by editing the registry. Use registry editor (Regedit.exe) to open the following key:

```
HKEY_LOCAL_MACHINE
    \Software
        \Microsoft
            \Windows NT
                \CurrentVersion
                    \Winlogon
```

and modify or create the following REG_SZ type values:

- DefaultDomainName
- DefaultUserName
- DefaultPassword
- AutoAdminLogon

Set AutoAdminLogon equal to 1 to enable automatic logon.

You can bypass the automatic logon process by holding down the Shift key upon startup or logoff.

Notes

Use extreme care when making changes to the registry, as improper use of Registry Editor can make your system unbootable.

Automatic Private IP Addressing (APIPA)

A feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that enables machines to be automatically assigned Internet Protocol (IP) addresses without the use of Dynamic Host Configuration Protocol (DHCP).

Overview

Automatic Private IP Addressing (APIPA) is designed for use on small networks where fewer than 25 machines are deployed. Such networks are too big to easily manage using static (manual) IP addressing and too small to warrant the use of a dedicated DHCP server for automatic IP addressing. APIPA was developed as an alternative to these two addressing methods.

If a Windows 2000, Windows XP, or Windows .NET Server client starts up and is configured for DHCP but finds no DHCP server to lease it an address, APIPA randomly assigns a machine an IP address. This randomly assigned address is in the range 169.254.x.y, which is reserved by Microsoft Corporation for this purpose and is not used on the Internet (in case your client has a direct connection to the Internet). A subnet mask of 255.255.0.0 is additionally assigned to the client.

Notes

One disadvantage of using APIPA is that machines whose addresses have been assigned using APIPA periodically poll the network for the presence of a DHCP server. Should a DHCP server be found, the machine yields its APIPA-generated address and leases a new address from the DHCP server. APIPA networks are thus particularly susceptible to interference from rogue DHCP servers, and APIPA should not be used in mission-critical or enterprise networks. You can disable this polling feature, however, by editing the registry.

APIPA is also available on the Windows 98SE platform.

Automatic System Recovery (ASR)

A feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that allows you to restore your system in the event of hard disk failure or corruption of system files.

Overview

Automatic System Recovery (ASR) is designed to replace the emergency repair disk (ERD) of Windows NT as the main tool for restoring systems after boot failures. ASR integrates the processes of repair, backup, and restore into a single recovery solution in the event of a disaster.

To use ASR, you must first configure it by running the Disaster Recovery Preparation Wizard, which is part of the Backup utility in Windows 2000, Windows XP, and Windows .NET Server. The resulting ASR disk contains configuration information that will be critical if you need to recover your system as a result of system volume damage or corruption. If you need to reinstall the system software, the ASR disk enables you to bring the system to the same configuration it had before the disaster.

Notes

Always run the Automatic System Recovery Wizard immediately before and after you make any changes to your system configuration using the Disk Management tool. If you do this, you will be able to return your system to the stable configuration that existed prior to your change.

Automatic Version Synchronization (AVS)

A feature of the Microsoft Internet Explorer Administration Kit (IEAK).

Overview

Automatic Version Synchronization (AVS) runs each time the IEAK administrator runs the IEAK Wizard and checks Microsoft Corporation's Web site for updates to Microsoft Internet Explorer. These updates are automatically downloaded and the administrator can distribute them to users throughout the enterprise.

Automation

A Microsoft technology that enables applications to expose their functionality to other applications.

Overview

Automation, formerly known as OLE Automation, is based on the Component Object Model (COM) and allows run-time binding of components. Automation is used exclusively by scripting languages, such as Microsoft Visual Basic for Applications (VBA), Microsoft Visual Basic Scripting Edition (VBScript), and Microsoft JScript, to access COM components that support Automation. The advantage of Automation is that it allows various languages to access COM components at run time. The drawbacks to Automation are that it is slow and that compile-time data type checking cannot be performed.

An application that exposes its functionality through Automation is called an Automation server. An application that communicates with the server through Automation is called an Automation controller or Automation client.

An Automation server is a COM component that typically implements the IDispatch interface. An Automation controller is a client that communicates with the Automation server, typically using IDispatch. IDispatch is a COM interface that allows a client to indirectly access all of the component's exposed methods and properties. Therefore, IDispatch enables a client to discover and access all a component's various methods and properties at run time through a single interface.

Notes

In the past, Automation required communication using the IDispatch interface. Now the term Automation is more generic and refers to the programmability of an application or component.

See Also: Automation controller; Automation server

Automation client

Also called an Automation controller, a client that accesses the functionality of an Automation server.

See: Automation controller

Automation controller

A client that accesses the functionality of an Automation server.

Overview

Automation is a way for one application to manipulate the exposed objects (properties and methods) of another application. Automation controllers are client applications that can manipulate the exposed objects of another application called an Automation server. Examples of Automation controllers include Microsoft Word, Microsoft Excel, and Microsoft Visual Basic.

There are two kinds of Automation clients:

- Clients that have static information about the properties and methods of the Automation server bound to them at compile time.
- Clients that dynamically obtain information about the properties and methods of the Automation server at run time. These clients do this by querying the Automation server's IDispatch interface.

See Also: Automation, Automation server

Automation server

A Component Object Model (COM) component that exposes its functionality to other applications.

Overview

An example of an Automation server might be a word processing program that can expose its spell-checking functions so that Automation controllers can access them. This allows the functionality of one program (the Automation server) to be used by other programs (the Automation clients or controllers).

An Automation server typically implements the IDispatch interface.

auto naming

A feature of Microsoft Exchange Server that enables administrators to configure how e-mail aliases and other information are automatically generated when mailboxes are created.

Overview

Using auto naming, you could, for example, automatically generate any of the following e-mail aliases for Jeff Smith's mailbox:

- JSmith
- JeffS
- JS

You could also devise some other custom naming scheme. These e-mail aliases then would be combined with the Domain Name System (DNS) domain name of the Exchange organization to form the user's standard e-mail address. For example, if the domain name of the company is northwind.microsoft.com, JSmith would be combined with it to form the e-mail address JSmith@northwind.microsoft.com.

autonomous system (AS)

A group of Internet Protocol (IP) networks administered under a single administrative (routing) policy.

Overview

An autonomous system (AS) is part of the routing infrastructure of a large IP internetwork. An AS is essentially a portion of a large internetwork whose routing is administered by a single authority. Typically, this means one AS per enterprise network. An autonomous system can be under the authority of a particular corporation or institution, or it can be defined by the uniform use of a particular routing protocol such as Open Shortest Path First (OSPF).

The Internet is the de facto example of a large IP internetwork divided into different autonomous systems such as AT&T Enhanced Network Services (formerly AT&T CERFnet), SprintLink, AlterNet, and so on. These autonomous systems are connected by the Internet's core routers, which use an exterior routing protocol called Border Gateway Protocol (BGP) for communication among themselves.

Each autonomous system must be identified using a globally unique number called an autonomous system

number (ASN). A BGP uses ASNs to avoid routing loops and implement policy-based routing on the Internet backbone. ASNs are required for autonomous systems connected to the Internet, and are obtained from Internet numbers registries such as the American Registry for Internet Numbers (ARIN) and the Asian-Pacific Network Information Center (APNIC). Autonomous systems exchange exterior routing information with one another by using these ASNs to identify themselves to other autonomous systems. Autonomous systems can be further subdivided into routing domains (areas) for more granular routing.

There are three basic types of autonomous systems:

- **Stub AS:** This AS is connected to only one other AS. A corporate network that is connected to an AS is considered to have the same AS number as the AS it is connected to.
- **Transit AS:** This AS is connected to more than one other AS and can be used for transit traffic between autonomous systems. A Transit AS is usually administered by a large Internet service provider (ISP).
- **Multihomed AS:** This AS is connected to more than one other AS but does not let transit traffic from another AS pass through itself. An example might be a corporate network with several Internet connections to different ISPs.

See Also: *autonomous system number (ASN), Border Gateway Protocol (BGP), routing*

autonomous system number (ASN)

A unique number used to identify an autonomous system (AS), that is, a network that can exchange exterior routing information with neighboring networks.

Overview

Every autonomous system (AS) connected to the global Internet must have a uniquely assigned autonomous system number (ASN). This ASN is required so that your AS can identify itself to other ASs on the Internet and exchange exterior routing information with their routers.

ASNs are 16-bit numbers that are assigned to networks by the American Registry for Internet Numbers (ARIN). As of 2000 there were more than 12,000 ASNs assigned to public and enterprise networks, and the number is rising rapidly as more and more enterprises implement multihoming, the use of multiple ISPs for providing Internet access for their networks. To obtain an ASN, contact ARIN and pay the one-time registration fee and the annual maintenance fee. Note that ISPs are not charged the annual maintenance fee for their ASNs.

See Also: *autonomous system (AS), multihoming*

autosensing

Technology by which a local area network (LAN) device can determine the characteristics of an attached device and configure itself accordingly.

Overview

As an example, a port on an autosensing 10/100-Mbps Ethernet switch can automatically detect whether the attached station has a 10-megabits per second (Mbps) or 100-Mbps network interface card (NIC). This is a useful feature that allows a combination of 10BaseT and Fast Ethernet connections in a single LAN.

Often during migration and system upgrades you will find a combination of slower, legacy networking equipment and faster, more modern devices. These devices might need to coexist for months or years, depending on the budget available for upgrades. Using autosensing hubs and switches makes this coexistence cheap and simple and allows a full upgrade to the faster configuration later—without purchasing additional equipment.

See Also: *hub, Ethernet switch*

availability

The degree to which network resources operate without interruptions resulting from scheduled maintenance or unexpected failure.

Overview

Availability has become an important issue in the modern Internet economy in which online electronic businesses are made or broken on the basis of reliable, fault-tolerant technologies.

Clustering is one tool for ensuring continuous uninterrupted 24 x 7 x 365 availability of network resources. Windows 2000, Windows XP, and Windows .NET Server include support for clustering that provides the basic platform for building high-availability e-business and electronic commerce applications that can compete in today's world. Cluster services can automatically detect when an application or server fails and quickly restart it on the surviving cluster node. Users connected to the server will experience only a brief pause in service.

AVS

Stands for Automatic Version Synchronization, a feature of the Microsoft Internet Explorer Administration Kit (IEAK).

See: Automatic Version Synchronization (AVS)

AWG

Stands for American Wire Gauge, a specification for the diameter of conducting wires.

Overview

The higher the AWG number, the thinner the wire. Category 5 (Cat5) cabling is usually AWG 24 wire (0.020 inch or 0.511 millimeter in diameter), while thicknet generally uses AWG 12 wire (0.080 inch or 2.050 millimeters in diameter). Twisted-pair telephone wire at the customer premises is typically 24 or 26 gauge, with 24 giving better performance for high-speed services such as Asymmetric Digital Subscriber Line (ADSL).

The table below shows some of the various AWG gauges for different diameters of wires. Note that the thinner the wire, the higher its electrical resistance and hence the shorter the transmission distance (because resistance varies inversely with thickness).

AWG Gauges for Various Diameters of Wires

<i>AWG Gauge</i>	<i>Diameter (Inches)</i>	<i>Diameter (Millimeters)</i>
12	0.080	2.050
14	0.064	1.630
16	0.051	1.290
18	0.040	1.020
20	0.032	0.813
22	0.025	0.643
24	0.020	0.511
30	0.010	0.254

AXFR request

A type of Domain Name System (DNS) request in which a secondary DNS server requests the update of information from a master DNS server.

Overview

An AXFR request always results in a full zone transfer. This can take time and use considerable network bandwidth if the zone files are large.

An alternative to AXFR is the incremental zone transfer protocol described in RFC 1995. Incremental zone transfers use an IXFR request and transfer only those portions of the zone file that have been changed.

Incremental zone transfers are supported by the DNS service running on Microsoft Windows 2000 and Windows .NET Server.

B2B

Stands for business-to-business and refers to e-commerce between different companies that have some sort of partnering arrangement, in contrast to B2C, or business-to-consumer, relationships in which individuals or companies purchase the products or services of another company.

Overview

Companies traditionally negotiate special business relationships with other companies that can provide them with the raw materials, tools, and services that they need for the success of their businesses. Such relationships are known as a value chain, which typically includes activities such as obtaining raw materials, processing these materials into finished products, shipping products to distributors, servicing customers, and marketing. To support a value chain, several business activities are essential, including procurement, research and development, manufacturing, and managing of human resources, operations, finances, and customer needs.

B2B is basically the use of the Internet to streamline and automate these business processes to enhance the value chain. This can result in streamlined business-cycle processes that are faster-to-market and in substantial cost savings by eliminating traditional paper-based invoicing and communications used in procurement channels. B2B can benefit companies in many different scenarios, including corporate purchasing, supply chain trading, and direct marketing.

Architecture

The technologies at the heart of B2B are the Internet, virtual private networks (VPNs) and Extensible Markup Language (XML). The Internet now provides a ubiquitous communications infrastructure that allows companies anywhere to connect with each other for exchange of business information. This can be accomplished

through a variety of means, including leased lines, xDSL, dial-up modem connections, and wireless satellite links. Just as the existing public switched telephone network (PSTN) catalyzed the explosive growth of fax technology after it was introduced, the Internet is revolutionizing the way business partners communicate to buy and sell goods and services.

VPNs are a popular technology that is widely used to secure communications over the Internet. Without the Internet itself, business partners would have to purchase costly leased lines for secure, reliable electronic communications between them, and many companies still use leased lines to support their Electronic Data Interchange (EDI) platforms. Using VPNs, however, companies can send these communications securely over the public Internet, allowing them to reduce costs by eliminating leased lines in favor of better-positioned technologies such as xDSL.

XML is a third component of most emerging B2B solutions platforms, as it provides a standardized way of encoding business communications for transmission over the Internet.

In addition to these technologies, other elements of successful B2B relationships include establishing credit relationships between companies and building B2B technology into legacy systems.

An emerging standard that may help promote B2B overall is an initiative from Ariba, Microsoft, and IBM called Universal Description, Discovery, and Integration (UDDI). UDDI is a proposed directory service that will make it easier for companies to find business partners that offer specific types of goods and services.

Implementation

You can implement B2B in three basic ways: build a custom solution, buy a packaged solution, or lease services from an online marketplace.

B

Building a custom B2B solution in conjunction with business partners is an approach that is often taken by large companies that require custom solutions that are integrated deeply into their existing legacy business systems and that have pockets deep enough to implement this type of solution. The disadvantage is the longer time-to-market period required for realizing benefits from this solution, and with the rapidly changing Internet economy this is a concern that needs to be seriously addressed by enterprise e-implementers. B2B solution providers pursuing this market segment are basically pursuing a vertical market in which they will handle a small number of large clients with extensive integration needs.

Buying an off-the-shelf B2B solution is another approach that can take several forms, from purchasing and deploying a software platform for developing B2B solutions such as Microsoft BizTalk Server to hiring a B2B consulting company to implement its own off-the-shelf solution. This approach is often taken by mid-sized companies with reduced capital availability and limited IT (information technology) resources, and especially so by dot-com startups seeking rapid time-to-market. A startup company might outsource all of their procurement needs to a B2B consulting service that will implement a packaged Web-based system for procurement and supply-chain management for them.

Leasing services from an existing B2B exchange is a third solution. Numerous online marketplaces supply B2B services for narrowly targeted market segments such as the food industry and the plastics industry. These B2B exchanges (or online marketplaces) provide packaged B2B solutions that include online catalog publishing services, secure transactions, direct marketing, and related services. An example is the food industry, where a B2B exchange can help grocery store chains manage procurement and speedy delivery of perishable goods.

A B2B exchange with a specific industry focus such as this is often called an Industry-Sponsored Marketplace (ISM), and a B2B solution provider with a more general focus of providing packaged B2B solutions for

small-sized or mid-sized companies is generally referred to as a “pure player.” These providers are competing in a horizontal market—that is, trying to gain as many customers as they can—and most first-generation B2B marketplaces took this approach to growing their ventures. Many of them provide B2B services on a transaction-fee basis, though there’s movement away from this model toward flat-rate pricing that makes B2B costs more predictable for clients.

B2B exchanges come in all flavors, from online shopping portals such as the healthcare industry portal PointStore, to industry-partnered ventures in which several companies form a cooperative exchange such as Hyatt International Corporation and Marriott International’s Avendra marketplace for the hospitality industry, to pure-play independent B2B exchanges such as Chemdex for the chemical industry built on B2B software from Commerce One and Ariba. Of these different approaches, the most successful ventures are generally the cooperatives in which the narrow industry focus and high alignment with partner needs generate the best results.

Marketplace

Commerce One and Ariba are two major players in the B2B marketplace arena, and between them they have more than 500 corporate customers. Ariba has partnered with IBM and i2 Technologies to provide software and services, and Commerce One has done the same with SAP AG.

Some of the bigger players in the ISM market include

- **e2Open:** An online marketplace for high technology supported by IBM, Nortel Networks, and others.
- **Altrade:** A B2B exchange developed by Altra Energy Technologies for the energy industry that includes high-profile partners such as Dow Chemical Company and ExxonMobil Corporation and which did over \$4 billion in trades in 1999.
- **Covisint:** An online supply-chain procurement marketplace being developed by the Big Three

automakers Ford Motors, General Motors, and DaimlerChrysler.

Companies that provide full-featured packaged B2B platforms include Ironside Technologies, Yantra Corporation, and many others.

Prospects

The future of the emerging B2B market overall is probably bright despite the shakeout of many startups that occurred in 2001. Many early proponents followed the horizontal market strategy of building one-size-fits-all B2B exchanges and then trying to attract customers along the “build it and they will come” paradigm. Unfortunately, most larger companies have legacy business systems that require a great deal of customization to participate effectively in B2B, and, as a result, most public B2B exchanges attracted only small and mid-sized companies whose resources were limited.

The main issues that tend to make many companies slow to jump on the bandwagon of public B2B exchanges are the unpredictable costs of transaction-based fees for involvement in these marketplaces, the complexity of integrating B2B solutions into existing supply chain systems (especially for companies that have progressed little in developing Web-based intranet and extranet solutions for their businesses), and issues relating to branding and customer loyalty that make suppliers reluctant to offer their wares at cut-rate prices in the new online marketplaces. As a result, successful B2B exchanges tend to be those that can build community—that is, a group of buyers and sellers loyal to one another. Private exchanges (those built upon preexisting business relationships) thus tend to fare well but offer few avenues for market growth for suppliers involved, and public exchanges offer a way of helping suppliers find new markets and new customers.

Another issue that has restrained many from the wholesale plunge into B2B is the snake-oil syndrome: new technologies breed startups that offer end-to-end solutions that are ready to implement “yesterday.” Due diligence is required of companies contemplating aligning themselves with a B2B solution or platform, and decision-makers

should obtain financials and customer testimonials to avoid getting caught in the web of fly-by-night operations that are here today and gone tomorrow.

With the failure of numerous public B2B marketplaces, companies that were early adopters are taking a more cautious view of further involvement, so that while recognizing the need to pursue B2B solutions in order to compete in the future economy, they are now more effectively taking care in investigating the financial viability of exchanges before jumping on board again. Nevertheless, while getting your company involved with a specific B2B provider is a tactical solution that requires good thought and due diligence, getting your company involved generally in B2B solutions is a strategic requirement for any company that hopes to survive in the Internet economy that is here and yet to come.

Notes

Microsoft Corporation has its own internal B2B solution called the Microsoft Market, which allows employees to quickly and easily procure goods and services from a wide variety of partner businesses. Microsoft Market has enabled Microsoft to lower average procurement costs by more than 90 percent.

Many B2B marketplaces provide procurement services based on either forward (sell-side) auctions which benefit suppliers or reverse (buy-side) auctions in which buyers submit a Request for Quotation (RFQ) and wait for the lowest bid to come in from suppliers. These services have not been as successful as anticipated, however, mainly because companies generally negotiate trusted long-term contractual business relationships with partners rather than just bid for the best-priced solution.

backbone

The portion of a network that ties different departmental networks into a single whole.

Overview

Backbones are primarily used in medium to large networks, such as those occupying a building or a group of buildings on a campus. The backbone carries the bulk of the network traffic and must be designed accordingly. Backbone designs generally fall into two basic categories:

- **Distributed backbone:** Refers to using cabling to join different departmental networks in a bus

topology or mesh topology. This cabling is referred to as backbone cabling, and it connects the hubs, switches, or routers of each network into a single whole. In a typical scenario, each floor or building might have a local area network (LAN) and wiring closet containing, among other things, a main hub or router. Backbone cabling is then run between floors or buildings, connecting the main hub or router for each department into a bus-style network (see illustration).

- **Collapsed backbone:** Refers to using cabling to directly join each departmental network's main hub or router using backbone cabling to a central hub, switch, or router in a star topology (see illustration). The central unit is often referred to as the collapsed backbone, although this term properly describes the entire configuration. The central unit can be located in the building's main equipment room or, in a campus scenario, in the IS (Information Services) department's building.

Backbone. Two basic types of network backbone: distributed and collapsed.

Distributed backbones generally have a greater degree of fault tolerance than collapsed ones, because the collapsed backbone unit forms a single point of failure. However, collapsed backbones usually have better traffic flow than distributed backbones because of the underlying star topology. Collapsed backbones generally offer better performance because of the reduced number of hops that traffic must make when passing between departmental LANs. Collapsed backbones are also easier to manage because they bring all the backbone switching and routing equipment into a single room or building. Collapsed backbones are used frequently for connecting departmental LANs within a single building, but less often for connecting building LANs across a campus network because of the increased distances and cabling costs.

Backbone cabling should have the highest bandwidth of any cabling in your network, since backbones are used to join together hubs, switches, and routers, linking departmental LANs or subnetworks into building-wide or campus-wide internetworks. In buildings, backbone cabling often refers to the vertical cabling running through the risers or elevator shafts that connects the hubs and switches in each floor's wiring closet. Depending on performance requirements, anticipated growth, and cost, any of the following might be suitable for backbone cabling:

- Category 5 (Cat5) unshielded twisted pair (UTP) cable
- Type 1A shielded twisted pair (STP) cable
- Thinnet coaxial cabling
- Multimode fiber-optic cabling
- Single-mode fiber-optic cabling

Notes

The term *backbone* is also used to refer to the collection of networking components (cabling, hubs, switches, and routers) that form the supporting network into which workgroup and departmental LANs are connected. A mesh topology is often used for network backbones to provide fault tolerance for critical high-speed data paths.

You should put considerable thought and planning into the design and implementation of your network's backbone, because the overall performance of networking services is largely dependent on the backbone's bandwidth and reliability. Design your backbone with network expansion in mind. Planning for growth is especially important if the cost of cable reinstallation is high. Fiber-optic cabling is preferred for most network backbones because of its high bandwidth, security, and resistance to electromagnetic interference.

backboning

Sending messages between similar messaging systems by using an intermediate messaging system of a different type.

Overview

A simple backboning example is the connecting of two or more Lotus cc:Mail postoffices using a Microsoft Exchange Server organization as the messaging backbone. By installing the cc:Mail Connector on Exchange Server, messaging connectivity can be established with connected cc:Mail postoffices. Messages can then be routed from one postoffice through the Exchange organization to other postoffices on the network.

Another example of backboning is connecting different sites in an Exchange Server organization using a public or private messaging network. Here are two possible scenarios:

- Using Simple Mail Transfer Protocol (SMTP) hosts on the Internet to connect Exchange sites.
- Using a public or private X.400 messaging system for connecting Exchange sites using the X.400 Connector.

① Using Exchange to backbone Lotus cc:Mail postoffices

② Backboning Exchange over the Internet SMTP system

Backboning. Connecting similar messaging systems by backboning over a different messaging system.

When using a public messaging backbone (or a private one owned by a different company) for connecting your Exchange sites, you should consider the following:

- Installing and configuring appropriate messaging connectors on suitable messaging bridgehead servers

- Establishing and maintaining directory replication between Exchange sites
- Handling background traffic from other users of the backbone
- Tuning messaging performance to optimize use of the backbone
- Implementing a suitable topology for the messaging backbone

For very large Exchange organizations, use a hub and spoke topology instead of a mesh topology. Hub and spoke topologies have less redundancy and fault tolerance, but mesh topologies have routing tables that grow exponentially with the number of sites involved. Mesh topologies for large organizations can lead to routing tables that are so large they degrade the performance of the message transfer agents, even on high-performance servers.

Notes

The term *backboning* is sometimes used to describe the core messaging paths set up for a large Exchange organization, regardless of whether messaging systems other than Exchange are involved.

background

A context for running applications or services on a computer.

Overview

A program that runs in the background is unnoticed while the user performs another task on a different program in the foreground. For example, a spreadsheet that calculates data could be hidden and running in the background while the user types a letter using a word processor program running in the foreground. If the user switches from the letter to the spreadsheet, the roles of the two programs become reversed.

Operating systems usually assign fewer CPU resources to background programs than to foreground ones. In Microsoft Windows 2000, Windows XP, and Windows .NET Server, the System utility in Control Panel offers you several Performance options on the Advanced tab

for optimizing performance between background and foreground tasks:

- **Applications:** Provides more CPU resources to the foreground program and allocates short, variable quanta to running applications
- **Background Services:** Divides CPU resources equally among the foreground program and any running background programs and allocates long, fixed-length quanta to applications

In addition, you can tune or enhance performance by modifying the total paging file size on all drives.

BackOffice

A suite of integrated server products from Microsoft Corporation.

Overview

The Microsoft BackOffice suite of server products is built upon the foundation of the Microsoft Windows 2000 Server and Advanced Server platform and provides a scalable, reliable solution for the needs of departments, branch offices, and medium-sized businesses. BackOffice is provided in an integrated package called BackOffice Server 2000, which provides tools for building directory, networking, messaging, Web services, database, proxy and firewall services, and Systems Network Architecture (SNA) host integration infrastructures.

BackOffice Server 2000 includes the following Microsoft server products:

- Windows 2000 Server or Advanced Server with Service Pack 1
- Exchange Server 2000
- SQL Server 2000
- Systems Management Server 2
- Internet Security and Acceleration Server 2000
- Host Integration Server 2000

In addition, BackOffice Server 2000 offers a host of additional tools for deploying and managing BackOffice components such as BackOffice Server management

consoles, various wizards, reporting tools, and Microsoft FrontPage and Microsoft Outlook client software. For additional information on each of the server applications listed above, see their respective articles elsewhere in this book.

Back Orifice

A remote administration tool for Microsoft Windows developed by the hacker group Cult of the Dead Cow.

Overview

Back Orifice was first released for the Microsoft Windows NT platform in 1997 by Cult of the Dead Cow (CDC), a professed hacker group. Although the tool is basically a form of Trojan horse that can be used to gain control of a target machine, it is also a full-featured remote administration system for computers that run Windows NT and Windows 2000.

Back Orifice consists of two parts:

- **Server component:** This is a small-footprint application that can be installed in a stealthy fashion on target systems and can also attach itself to any Windows executable on the target machine or run as a separate service using any name designed. The server runs invisibly in the background and is not visible to users logged on to the target machine even in the task list or close-program dialog box.
- **Client component:** This application is used by the administrator (or hacker) to control the remote Windows 2000 computer. The client component can be used either in graphical user interface (GUI) or command-line mode and can be used to send commands to the server component to perform directory listings, copy or delete files, display or kill running processes,

B

log all keystrokes entered at the remote machine's console, reboot or lock the system, edit the registry, and perform other actions. By default the client sends commands to the server through User Datagram Protocol (UDP) port 31337 but can be configured to use any available UDP port instead.

Back Orifice is a powerful remote administration tool, but because of its stealth features it is also a serious threat to systems running Windows NT and Windows 2000. Administrators who are concerned about this threat should consult article Q237280 in the Knowledge Base on Microsoft TechNet, which explains how to detect when the server component of Back Orifice is present on a system and how to remove it.

backup

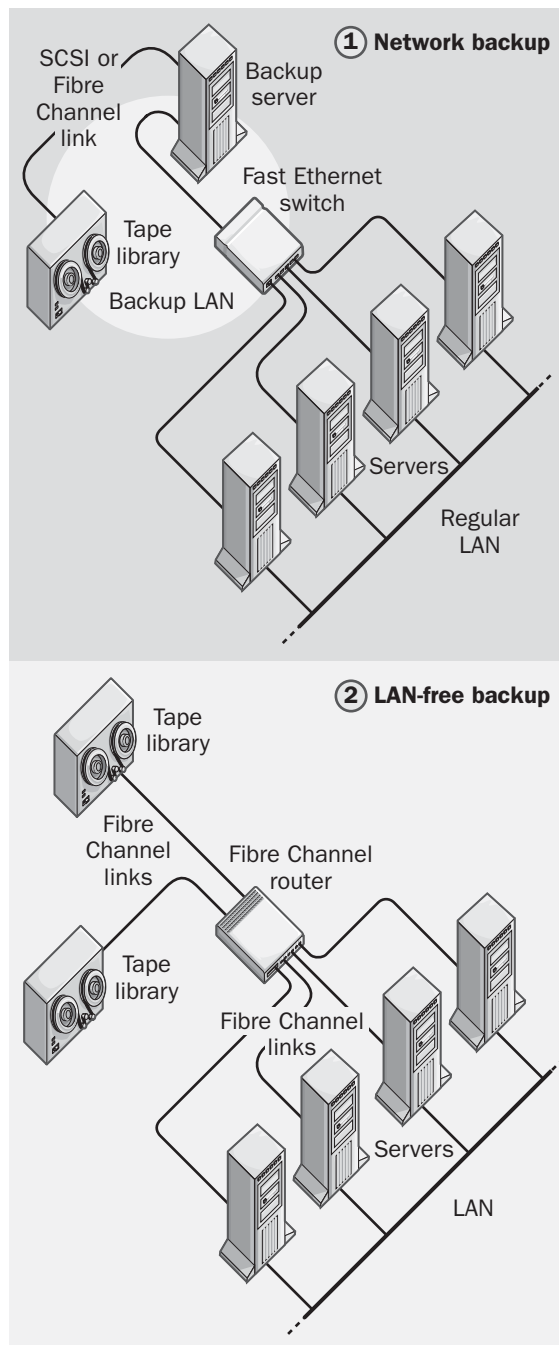

The process of making reliable copies of important data so that the data can be recovered in the event of a disaster.

Overview

Performing regular backups is perhaps the system or network administrator's least glamorous but most important task. Data loss on a corporate network can occur for various reasons, including

- Disk failures caused by hardware failure, power outages, or improper use
- Network problems leading to lost packets that are not acknowledged because of router congestion or other situations
- Virus infection, resulting in corrupted files
- Sabotage by hackers or disgruntled employees, resulting in erased data
- Theft of hardware from the premises

In each of these scenarios, having reliable backups of your company data is essential to recover from the disaster and continue normal business functioning.

Backup. Network and LAN-free backup scenarios in the enterprise.

At the enterprise level, backups can be performed using a variety of technologies, each of which have their own advantages. These technologies are a blend of backup device hardware and how these devices are implemented. The next section of this article looks at a few common scenarios. First, backup solutions can be characterized by the devices used to store the backed-up data. These devices can include

- **Tape drives:** A tape drive is a device that stores data on magnetic tape. Many kinds of tape drives and tape formats are supported by different vendors, and these are discussed more fully in the articles “tape drive” and “tape format” elsewhere in this book. Generally speaking, however, tape drives have capacities in the tens of gigabytes range and are suitable for backing up data from individual servers or small groups of servers.
- **Tape libraries:** A tape library consists of a set of tape drives, a large collection of tapes, and a robotic mechanism for loading and unloading tapes into drives. Tape libraries are common in large companies and can typically store several terabytes (one terabyte equals 1000 gigabytes) of data from groups of servers. For more information, see the article “tape library” elsewhere in this book.
- **Optical drives:** Another medium for backing up data is optical drives, which range from simple CD-R/W drives to DVD-W drives and libraries containing many such drives. Optical drives are not as common as tape drives and libraries.
- **Storage appliances:** These are generally rack-mountable black-box solutions in which the underlying operation is not important. Storage appliances are generally used for live data storage but can also be used for small-scale backup purposes.
- **Storage Area Networks (SANs):** While SANs are primarily used for live storage of data, they can also be used for archiving backup data. See the article “storage area network (SAN)” elsewhere in this book for more information.
- **Server-based backups:** In this scenario each server that holds valuable data has a tape drive directly attached to it, usually through a Small Computer System Interface (SCSI) connection. The disadvantage of this scenario is that it scales poorly for large companies—administrators would need to run around each morning to collect tapes from drives scattered all over the network.
- **Network backups:** This is the most common scenario in most large companies. In a typical network backup scenario, a group of servers on a local area network (LAN) are connected using a second network interface card (NIC) in each server to a separate LAN dedicated for backup purposes. This dedicated backup LAN is concentrated using a Fast or Gigabit Ethernet Switch, which is also connected to a dedicated server called the backup server. The backup server has special software running on it that initiates and manages the job of backing up data on the production servers. The backup server itself is then connected by SCSI or FiberChannel to a tape library (see illustration).
- **LAN-free backup:** This is a simplified form of network backup in which there’s no second backup LAN. Instead, fiber channel cards are added to servers needing to be backed up and these are connected using fiber-optic cabling to a fiber-channel router, which then forwards the information directly over Fibre Channel links to tape libraries (see illustration). LAN-free backup is an emerging approach that is gaining in popularity due to its simplicity and high performance.
- **Serverless backups:** This is a further refinement of LAN-free backups that takes the actual task of processing the backup from the servers and moves it to a Fibre Channel switch or router used to connect the servers to the tape libraries. This can provide significant relief to the servers since generating backups is a processor-intensive and memory-intensive job that limits other functions they can perform while the backup is occurring. Serverless backup solutions are just emerging in the marketplace.
- **Storage over IP:** This technology backs up data from network servers directly to backup devices such as tape libraries and SANs using only an Ethernet

Besides these different backup devices, there are also various ways of implementing them for backing up data from network servers:

B

network. No backup server is required to convert the data from Ethernet frames for transmission over SCSI or Fibre Channel connections to the backup device. Storage over IP is an emerging technology that promises to have a large impact on the backup market, and it is discussed further in the article “storage over IP” elsewhere in this book.

- **Internet backups:** Backups can also be outsourced over the Internet to a Storage Service Provider (SSP) that is responsible for managing actual backup hardware and securely storing your data. For more information on this, see the article “televaulting” elsewhere in this book.

Finally, a third component of a backup system is the backup software itself. Some of the more popular backup software products used in the enterprise include

- ArcServeIT from Computer Associates
- Backup Exec and NetBackup from VERITAS Software Corporation
- Legato NetWorker from Legato Systems
- Storage Manager from Tivoli Systems
- Backup Express from Syncsort
- Hiback and Hibars from Hicomp Software Systems

Implementation

Instituting a regular backup plan is one of the main components of a company’s disaster recovery policy (see the article “disaster recovery” elsewhere in this book for more information), and the importance of doing so cannot be stressed enough. To guard against these unexpected losses of data—or rather, to prepare for them, since they are, to a certain extent, inevitable—establish a disaster recovery policy that includes a reliable backup plan. In today’s business world, where data is the lifeblood of the enterprise, a comprehensive plan is essential. The following steps are recommended when creating such a plan:

- Decide what kind of backup storage devices to use. Options range from small digital audio tape (DAT) drive units capable of backing up several gigabytes of data to large automated tape libraries capable of handling terabytes of centralized data storage.

Other backup options include optical storage libraries and removable disks such as Iomega’s Zip drive disks or Imation SuperDisk disks.

- Decide whether to back up servers with dedicated, locally connected storage devices or over the network to centralized backup libraries. Network backup systems suffer from a single point of failure (the network itself) but are simpler to administer than a multitude of individual backup units.
- Decide whether individual users’ workstations should also be backed up. A more cost-effective option is to educate users to always save their work on a network share located on a server that is regularly backed up.
- Decide how to secure the storage of backup tapes and other media. Will duplicate copies be stored both on-site (for easy access if a restore is needed) and off-site (in case the company’s building burns down)? Make sure the storage facilities are climate-controlled and secure.
- Decide what kind of backup strategy to employ. A backup strategy is a combination of a backup schedule and various backup types, including normal, copy, incremental, differential, and daily copy backup types. Also consider whether you will verify all tapes immediately after each backup is performed. For further information, see the articles “backup strategy” and “backup type” elsewhere in this chapter.
- Assign various aspects of the backup procedure to the responsible party. One option some companies now use is to back up data over the Internet to a third-party backup service provider that stores and maintains the backed-up data. This method involves issues of trust and of the Internet connection as a point of failure.
- Test backups periodically to ensure that they are actually readable. Nothing is worse than thinking you have a backup when in fact it is unreadable.

Notes

To enable administrators to perform regular backups, Microsoft Corporation includes backup utilities with all

versions of Microsoft Windows, such as the Backup tool in Windows XP.

backup agent

A service that can be installed on a computer to allow files and folders stored on the computer to be backed up remotely over the network.

Overview

Backup agents enable backups to be performed across an entire network from a centralized location. In networks that utilize this type of storage retention architecture, where a backup agent is installed on each server, files are backed up over the network to a central storage location, which in enterprise environments is usually a tape library or some type of Network Attached Storage (NAS). This approach to backups makes it easier to manage enterprise storage requirements even for large scale corporate networks and Internet service providers (ISPs).

Backup agents are specific to the type of backup software being used and are usually supplied with that software when you purchase it from a vendor. Once an agent is installed on a computer, you can back it up over the network as easily as if a tape drive were connected directly to the computer.

backup browser

A Windows 2000, Windows XP, and Windows .NET Server computer that participates in the Computer Browser service.

Overview

A backup browser is a computer that obtains a copy of the browse list from the master browser. The browse list contains information about which shared resources are available to client machines on the network and about which domains are on the network. Backup browsers automatically contact the master browser every 12 minutes to request a copy of the browse list. If the contact is successful, the master browser issues the list to the backup browser. If the backup browser cannot contact

the master browser, it starts a browser election to force a new master browser to be selected.

Once the backup browser has obtained the browse list, it caches the list and distributes it to any client that requests it. To request the browse list from a backup browser, a client calls the NetServerEnum application programming interface (API) on the backup browser.

Backup browser. How a client obtains the browse list from a backup browser.

Notes

There will be one backup browser for every 32 systems in a given domain or workgroup on the network. The Computer Browser service determines the number of backup browsers necessary to ensure that clients can have efficient access to network resources.

backup catalog

A representation of the results of performing a backup of servers on a network.

Overview

Backup software, such as the Backup tool in Microsoft Windows 2000, Windows XP, and Windows .NET Server, creates catalogs so that the location and properties of backed-up files are documented and can be found easily when a restore needs to be performed. Windows 2000, Windows XP, and Windows .NET Server Backup stores its catalogs on the backup storage media themselves. These catalogs are then loaded into memory when the program is run. Catalogs can also be saved to disk and printed for documentation purposes.

B

Windows 2000, Windows XP, and Windows .NET Server Backup creates two different types of backup catalogs:

- **Tape catalog:** Lists the details of all backup sets that have been stored on the tape. If a backup operation spans several tapes, the tape catalog is located on the last tape of the series, because it is created at the end of the backup operation.
- **Backup set catalog:** Lists the details of files and folders included in a specific backup set. A backup set catalog is saved at the end of each backup set on the tape. This catalog is used by the Windows 2000, Windows XP, and Windows .NET Server Backup program to store a summary of the file and directory information for the backup set, the number of tapes in the backup set, and the date on which the backup was performed.

backup domain controller (BDC)

A Microsoft Windows NT domain controller containing a read-only copy of the Security Accounts Manager (SAM) database.

Overview

On the Windows NT platform, the only writable copy of the SAM database is located on the primary domain controller (PDC). In addition to this PDC, a Windows NT domain can have zero or more backup domain controllers (BDCs) as well. These BDCs are used to provide load balancing and redundancy for network authentication. These BDCs periodically undergo directory synchronization with the PDC by retrieving a copy of the directory database from the PDC.

Two choices for locating BDCs for user logons in WAN situations:

Backup domain controller (BDC). Different ways to deploy a BDC over a WAN link.

Every Windows NT network should have at least one BDC for fault tolerance. If the PDC fails, the BDC can be promoted to take its place. One BDC can support approximately 2000 users on a network, but many factors can affect this figure.

Note that a BDC can perform logon validation and authentication as a PDC can, but it cannot manage accounts—for example, it cannot change user passwords.

Implementation

The placement of BDCs in wide area networks (WANs) that are based on Windows NT is an important issue. In a master domain model scenario, user accounts are centralized in a master domain located at company headquarters, but users and shared network resources are distributed in resource domains located at branch offices in different locations. The users in this scenario must log on to the master domain in order to access resources in the enterprise. There are two ways of facilitating this:

- Locate all BDCs belonging to the master domain at headquarters. Unfortunately, when users at the branch offices want to log on, they will have to use the relatively slow WAN link to do so. The additional logon traffic can cause congestion on the WAN link, particularly at certain times of the day.
- Locate one or more BDCs belonging to the master domain at each branch office (resource domain). This will facilitate logons by users located at branch offices, since they can log on to one of these BDCs locally instead of being validated over the relatively slow WAN link by a domain controller at headquarters. However, directory replication traffic between the BDCs located at the branch offices and the PDC at headquarters can cause congestion over the WAN links. To make directory synchronization more efficient over the WAN link, registry parameters such as ReplicationGovernor and ChangeLogSize can be adjusted and batch files can be scheduled using the

at command to configure different replication rates at different times of the day.

Backup Operator

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a user who is assigned the responsibility of backing up and restoring servers on a network.

Overview

To make an individual a Backup Operator, simply make him a member of the Backup Operators group. Backup Operators can exist on Windows NT domain controllers, on member servers, and on workstations. In Windows 2000, Windows XP, and Windows .NET Server, Backup Operators are members who have a similar function and belong to the built-in group called the Backup Operators built-in group.

Backup Operators have the preassigned right to log on locally to a computer and to back up and restore files and directories on the system. Backup Operators also have the right to shut down the system. Backup Operators do not need permissions assigned to them in order to back up a particular file or directory—they have a broad system right to do so.

Notes

Backup Operators should be assigned only in enterprise-level networking environments. In small to medium-sized networking environments, backing up and restoring servers is usually the responsibility of the administrator.

See Also: Backup Operators built-in group, built-in group

Backup Operators built-in group

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a built-in group for containing users who need privileges to back up servers on the network.

B

Overview

Backup Operators is a built-in group existing on all Windows 2000–, Windows XP–, and Windows .NET Server–based servers and workstations. The Backup Operators built-in group is a local group with the following preassigned rights:

- Log on locally
- Back up files and directories
- Restore files and directories
- Shut down the system

Notes

If you want a user to be able to back up files and directories on any domain controller in a domain, place the user in the Backup Operators group on any domain controller. Since all domain controllers share the same directory database, the user will be a member of the Backup Operators built-in group for all domain controllers. However, if you want a user to be able to back up a member server, place the user in the Backup Operators built-in group that is a local group on that particular member server.

backup set

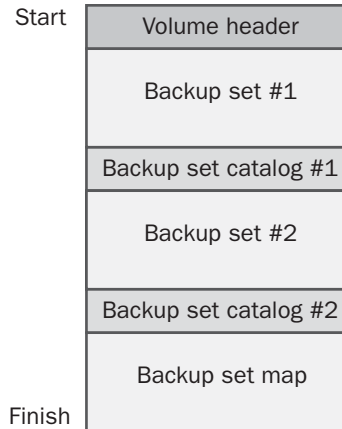

A collection of files and folders on a backup media that were saved in a single Microsoft Windows 2000, Windows XP, and Windows .NET Server Backup operation.

Overview

There are several options for creating backup sets in Windows 2000, Windows XP, and Windows .NET Server:

- Multiple backup sets can be saved on a single backup tape by appending each new set to the last one.
- A backup set can span multiple tapes if you have a large quantity of information to back up.
- Tapes can be overwritten so that a new backup set replaces the old one.

Backup tape

Backup set. A representation of a backup set.

Windows 2000, Windows XP, and Windows .NET Server Backup creates a backup set catalog for each backup set. This catalog lists the various files and directories that have been backed up, and you can use it for restoring individual files or directories or print it for documentation purposes. The backup set catalog is saved at the end of each backup set on the tape. A backup set map at the end of the tape locates all backup sets on the tape.

Notes

A copy of the local system's registry can also be included in the backup set for a Windows 2000, Windows XP, and Windows .NET Server system. Backup sets are described with friendly names that can be up to 32 characters long.

backup strategy

A plan for performing backups to ensure against data loss.

Overview

Successful backup strategies take the following issues into account:

- The various backup types that can be performed
- The need to archive tapes for long-term data security
- The time needed to perform backups and restores

- The cost of tapes
- The cost of losing data

There's no one right way to implement a backup strategy for resources on a network of computers. To select the best backup strategy for your network, you must consider each of the items in the preceding list and balance them against one another. Your strategy should be simple, efficient, and reliable. The following table shows some examples of backup strategies:

Possible Backup Strategies

<i>Backup Strategy</i>	<i>Advantages</i>	<i>Disadvantages</i>
Normal backups Monday through Friday.	Most secure—every tape contains all backed up files	Longest time to back up
Normal backup Monday; differential backups Tuesday through Friday.	Less time to restore	More time to back up
Normal backup Monday; incremental backups Tuesday through Friday.	Less time to back up	More time to restore
Use a separate tape for each weekday and archive Monday's full backup tape weekly or monthly.	Less chance of data loss	Higher cost, since more tapes are needed
Use the same tape for each weekday and archive the tape each week or month.	Cheaper—only one tape required per week or month	Greater chance of data loss, since using only one tape

backup type

A particular method for performing a backup of files and directories.

Overview

Each type of backup has a different function in an overall backup plan. Most network backup software (such

as Microsoft Windows 2000, Windows XP, and Windows .NET Server Backup) supports five backup methods:

- **Normal backup:** Backs up volumes, folders, and files that have been specified by the administrator. Normal backups are the fastest and easiest to restore. Normal backups are sometimes referred to as "full backups." Use a normal backup when you want to ensure that all your critical system and data files are backed up in a single operation. If your backup cycle consists only of normal backups and you need to perform a restore, you need to use only the most recent normal backup to do so.
- **Copy backup:** Primarily used to produce an additional copy of a backup—for example, a copy to send to the accounting department for monthly archiving and reporting. While a copy backup backs up the same files as a normal backup, there is a difference between the two operations. Performing a normal backup clears the archive bit on each backed-up file and marks them as having been backed up. A copy backup, however, does not modify the archive bit on the files backed up. In other words, you can perform a copy backup at any time in a backup cycle without interrupting the cycle in any way—the copy backup is distinct from the backup cycle and is not required when a restore is performed from the cycle's set of tapes.
- **Incremental backup:** Backs up only files that have been created or modified since the last normal or incremental backup. Files that are backed up in an incremental backup have their archive attributes cleared in order to indicate that they have been backed up. Using a combination of normal and incremental backups takes less time and uses less storage space than performing only normal backups. However, if you need to perform a restore, you typically need to use the normal backup plus every incremental backup from the current backup cycle to do so.
- **Differential backup:** Copies those files that have been created or changed since the last normal or incremental backup. Files that are backed up by a

B

differential backup do not have their archive attributes cleared, which means that these files will be backed up again in any succeeding differential backups. Differential backups are cumulative with regard to changes—that is, each differential backup in a given backup cycle contains all the files from the last differential backup, plus any files that have been modified since the last differential backup. Thus, if you need to perform a restore, you will typically need to use only the normal backup and the most recent differential backup from the current backup cycle to do so.

- **Daily copy backup:** Copies all files that have been modified on the day the daily copy backup is performed. This method is sometimes used to make a copy of all files a user worked on in a day so that he or she can take them home to work on. Like a copy backup, the daily copy backup does not modify the archive bit of the files backed up; therefore, the daily copy backup does not interrupt the backup cycle in any way.

Notes

Different types of backup operations have different effects on the archive attributes of the files and directories they back up. A backup operation marks the archive attribute by clearing it to indicate that the file has been backed up. If the file is later modified in some way, its archive attribute is set (unmarked). The following table shows what each type of backup operation does to the archive attribute.

Effects of Backup Operations on the Archive Attribute

<i>Backup Type</i>	<i>Archive Attribute</i>
Normal	Cleared
Copy	No effect
Incremental	Cleared
Differential	No effect
Daily copy	No effect

Backup Wizard

A wizard that is part of the Microsoft Windows 2000, Windows XP, and Windows .NET Server Backup tool.

Overview

You can use the Backup Wizard to configure, schedule, and execute a backup. The Backup Wizard starts by letting you choose among the following:

- Backing up all files on the computer on which it is running.
- Backing up files and folders that you specify. These files and folders can be either on the local computer or on any shared location on the network.
- Backing up Active Directory directory service information and the registry on the computer on which the wizard is running. Active Directory can be backed up only on a domain controller.

The wizard then leads you through the process of specifying a backup location and other advanced backup options, such as verification, compression, and remote storage. You can also schedule a backup job to run unattended at a later time when users have stopped working and all files are closed.

BACP

Stands for Bandwidth Allocation Control Protocol, an enhanced version of Bandwidth Allocation Protocol (BAP), a protocol that manages bandwidth for Multi-link Point-to-Point Protocol (MPPP) connections.

balanced line

An electrical cable consisting of pairs of conductors that have identical electrical characteristics with respect to each other and with respect to ground.

Overview

In a balanced line, both of the two wires are carrying current at any given instant. However, at any particular moment, the directions of the current in the wires are

opposite each other. This condition is also described by saying that the currents in the wires are 180 degrees out of phase with each other at any given moment.

Both wires have voltages that are above ground potential, but the potentials of the wires are different with respect to ground, resulting in a flow of current. The wire pair is twisted in order to ensure that the electromagnetic radiation produced by both wires is effectively canceled out, reducing the overall electromagnetic interference (EMI) produced by the wires and reducing their sensitivity to induced currents from external sources of EMI.

The most common example in computer networking is the twisted-pair cabling used in 10BaseT Ethernet networks.

Notes

A balun can be used to connect a balanced line to an unbalanced line.

See Also: balun, unbalanced line

balun

Stands for balanced unbalanced, a device used to connect balanced lines and unbalanced lines.

Overview

Balanced and unbalanced lines have different electrical characteristics that prevent them from simply being connected to each other. A balun matches these different characteristics by providing impedance transformation between the two different lines.

Balun. An example of a coaxial-to-twisted-pair balun.

Baluns can be used for various types of connections between different wiring systems:

- **Twisted-pair cabling to coaxial cabling:** Typically used for connecting 10BaseT networks with 3270 equipment running on coax or twinax networks
- **Twisted-pair cabling to Token Ring cabling:** Used for matching Token Ring Type 1 cabling to standard unshielded twisted-pair (UTP) cabling to connect 10BaseT or faster hubs or adapters with RJ-45 ports into a Token Ring network
- **Asynchronous Transfer Mode (ATM) cabling to Token Ring cabling:** Used for connecting Token Ring networks to high-speed ATM hubs in campus backbone networks

bandwidth

The information-carrying capacity of a signal or technology.

Overview

By definition, bandwidth equals the difference between the highest and lowest frequencies in a given range of frequencies. For example, if the lowest and highest frequencies a telephone line can carry are 300 hertz (Hz) and 3300 Hz, the bandwidth of the telephone line is $3300 - 300 = 3000$ Hz, or 3 kilohertz (kHz).

The above definition of bandwidth applies to any signaling system, analog or digital. With digital systems such as computer data networks, the term *bandwidth* is often used to describe the capacity of a communication channel for carrying signals. The greater the bandwidth, the more data can be transferred in a given time. Since bandwidth is here synonymous with information, and digital information is conveyed in bits (1=on and 0=off), bandwidth for such systems is usually expressed in bits per second (bps) or some multiple thereof (including Kbps, Mbps, Gbps, and Tbps). This rate of flow of information in bits per second is more properly termed “throughput,” but bandwidth is the usual expression used in popular literature.

B

Shannon's Law can be used to determine the information-carrying capacity of a transmission channel as follows:

$$(\text{Throughput in bps}) = (\text{Bandwidth in Hz}) \times \log_2 [1 + R]$$

where

$$R = (\text{Signal power in Watts}) / (\text{Noise power in Watts})$$

This formula is only approximate since it does not take into account the medium's transmission properties and other considerations. The significant thing to notice, however, is that as noise (due to crosstalk, interference, or some other source) increases, the channel's capacity to carry information decreases.

For fiber-optic cabling, the bandwidth is usually expressed in units of MHz-km. For example, a cable rated at 500 MHz-km could carry 500 Mbps of data a distance of 1 kilometer (km), 250 Mbps of data a distance of 2 kilometers, 100 Mbps of data a distance of 5 kilometers, and so on. A similar explanation holds for measurements in units of MHz-miles.

Notes

Adequate bandwidth is a prerequisite for reliable communications, and ensuring sufficient bandwidth in today's Internet economy often drives upgrades for enterprise networks. When a new bandwidth need arises, such as deployment of streaming media across a network, the obvious solution may seem to be to "throw bandwidth at the problem," that is, to spend money on upgrading the network infrastructure from Ethernet to Fast Ethernet to Gigabit Ethernet (GbE) and beyond. This is really only one solution—another, sometimes better, approach is to implement Quality of Service (QoS) mechanisms to prioritize traffic so that certain forms of traffic receive preferential transport over less important forms. QoS is an elegant solution that sidesteps the brute-force approach of simply adding more bandwidth, but QoS can be difficult to configure and manage. Although Asynchronous Transport Mode (ATM) networks have the advantage of having QoS built into their operational fabric, the far more common Ethernet networks require new protocols such as DiffServ and Resource Reservation Setup Protocol (RSVP) to be implemented to support even rudimentary

QoS features. And with the rapidly dropping prices of GbE switching gear and the appearance of 10 GbE on the horizon, simply adding more bandwidth when it is needed is still the most common solution for most large companies.

Bandwidth Allocation Control Protocol (BACP)

An enhanced version of Bandwidth Allocation Protocol (BAP), a protocol that manages bandwidth for Multilink Point-to-Point Protocol (MPPP) connections.

Overview

Although BAP dynamically controls how bandwidth can be allocated for Multilink Point-to-Point Protocol (MPPP) connections, a condition can sometimes occur in which both hosts at the two ends of a MPPP connection try to add or remove an additional link at the same time. The Bandwidth Allocation Control Protocol (BACP) is an enhanced version of BAP that is designed to handle such a scenario. It does this by establishing ahead of time which MPPP host is the favored peer, that is, the one whose BAP request will be honored in case of a collision of two requests.

See Also: *Bandwidth Allocation Protocol (BAP), Multilink Point-to-Point Protocol (MPPP)*

Bandwidth Allocation Protocol (BAP)

An offshoot of Multilink Point-to-Point Protocol (MPPP) that allows new links to be added or removed dynamically when needed.

Overview

The Bandwidth Allocation Protocol (BAP) dynamically controls how bandwidth can be allocated for multilink connections using the Point-to-Point Protocol (PPP). BAP makes multilink remote access (RAS) connections more efficient by allocating lines only as required, thus eliminating wasted bandwidth. This can be especially useful if the telecommunications carrier provisioning the PPP connection charges by the amount of bandwidth being utilized by the customer.

BAP allows the administrator to configure the PPP server to specify which particular MPPP lines can be added or dropped. The administrator also specifies which bandwidth thresholds must be crossed before additional lines are added or existing ones are dropped. BAP is especially useful over Integrated Services Digital Network (ISDN) connections, because these dial-up services can almost instantly add or drop lines.

Notes

BAP is included in Microsoft Windows 2000 and Windows .NET Server as an enhancement to the Routing and Remote Access Service (RRAS) of Windows NT 4. BAP is outlined in detail in RFC 2125.

bandwidth on demand

Any networking or telecommunications technology that provides both a permanent, dedicated connection and the capability of quickly increasing bandwidth when needed by users.

Overview

Many telecommunications devices incorporate bandwidth-on-demand features of various types. For example, some Integrated Services Digital Network (ISDN) devices used for Basic Rate Interface ISDN (BRI-ISDN) can be configured to use the second ISDN B channel only when the utilization of the first channel exceeds a certain threshold. If this threshold is exceeded for a specified period of time, the second B channel automatically opens up to facilitate and speed data transfer. Once the data rate has dropped below the threshold, the second B channel shuts down until it is needed again. The ISDN technology for accomplishing this combining of channels is called bonding. Many Asynchronous Transfer Mode (ATM) products also support various bandwidth-on-demand features.

Bandwidth-on-demand technologies are typically used in bursty networking situations in which high transmission speeds and capacities are required for transporting video, voice, and data on common networking circuits. Bandwidth-on-demand configurations often involve a

mix of leased-line services and circuit-switched telecommunications services, and they can save users money by opening additional circuits only on an as-needed basis. Networks that make use of bandwidth on demand can be designed to supply additional bandwidth under conditions such as

- Exceeding a specified threshold of network traffic
- Scheduling for expected peak periods of the day
- Failover in case the permanent link goes down

bandwidth throttling

Generally, any networking technology that controls the amount of network bandwidth used by servers, applications, or network communication paths.

Overview

In the context of Microsoft Internet Information Services (IIS), for example, bandwidth throttling is a technique for controlling the amount of network bandwidth used by individual Web sites hosted on the server. You can use bandwidth throttling to prevent hits on a popular site from overwhelming the server and preventing other sites hosted on the server from being accessed by clients.

For example, if five Web sites are being hosted on a single machine running IIS but one of them is extremely popular, the other sites might get starved for bandwidth and users might have difficulty connecting to them. In order to rectify this situation, a specific maximum bandwidth level can be allocated to the popular site with the Internet Services Manager snap-in used for administering IIS using the Microsoft Management Console (MMC). If this maximum bandwidth is exceeded, no further connections to that site are allowed until the bandwidth utilization level drops below the threshold. This allows the unallocated bandwidth to be shared among the remaining less popular sites so that users can connect to them.

Banyan VINES

Stands for Banyan Virtual Integrated Network Service (VINES), a legacy network operating system (NOS) for building enterprise-level networks.

Overview

VINES was originally based on a proprietary family of protocols that was derived from the Xerox Network Systems (XNS) protocol. VINES uses a client/server distributed networking architecture for allowing clients to access network resources on servers over the network. VINES includes such features as

- Basic file and print sharing
- A distributed directory service called StreetTalk for managing networks
- Support for the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol
- Graphical administration tools
- Support for Simple Network Management Protocol (SNMP) management

VINES includes clients for MS-DOS, OS/2, Microsoft Windows, and Macintosh platforms as well as optional applications for integrating Windows NT, AppleTalk, Novell, and UNIX networks into existing VINES-based networks.

VINES is built on a client/server model in which clients can make requests for services from servers on the network. The VINES protocol stack consists of five basic layers that map to the seven-layer Open Systems Interconnection (OSI) reference model as follows:

- **Physical and data-link layers:** VINES can operate over Ethernet, Token Ring, X.25, and other types of networking architectures.
- **Network layer:** The main protocol here is the VINES Internetwork Protocol (VIP), which is similar in function to the IP of the TCP/IP protocol suite. VIP encapsulates data and addresses it using a 48-bit address that contains a 32-bit network number and a 16-bit host number. Dynamic address assignment and address resolution are performed

using VINES servers, which are referred to as service nodes. VINES clients obtain their addresses dynamically from the nearest server on the network. Multihomed servers function as routers, and routing tables are maintained by periodic announcements from clients and servers. Other network layer protocols include an Address Resolution Protocol (ARP), an Internet Control Protocol (ICP), and a Routing Table Protocol (RTP).

- **Transport layer:** For reliable delivery of data using acknowledgments and sequence numbers, VINES uses its Reliable Message Service. Another service, the Unreliable Datagram Service, supports only best-effort delivery of packets. Finally the Data Stream Service can be used to transmit large amounts of data using virtual circuits with flow-control mechanisms.
- **Session and presentation layers:** VINES implements the standard remote procedure call (RPC) mechanism for enabling communication between VINES client and server components on different stations on the network.
- **Application layer:** VINES supports standard file and print services, directory services (StreetTalk), and a number of other application layer services and protocols.

Notes

When connecting Windows 95 or Windows 98 clients to a VINES-based network, use the 32-bit client for Windows that comes with VINES instead of the 16-bit VINES client included with Windows 95 and Windows 98.

baseband transmission

A signaling technology that sends digital signals over a single frequency as discrete electrical pulses.

Overview

The entire bandwidth of a baseband system carries only one data signal and is generally less than the amount of bandwidth available on a broadband transmission system. The baseband signal is bidirectional so that a baseband system can transmit and receive signals simultaneously.

Baseband signals can be regenerated using repeaters in order to travel longer distances before weakening and becoming unusable because of attenuation. Baseband transmission technologies do not use modulation but often use time-division multiplexing (TDM) to accommodate multiple channels over a single baseband transmission line.

Common local area network (LAN) networking technologies such as Ethernet use baseband transmission technology. All stations on a baseband network share the same transmission medium, and they use the entire bandwidth of that medium for transmission. As a result, only one device on a baseband network can transmit at a given instant, resulting in the need for a media access control method to handle contention.

baseline

A set of data that indicates normal usage of monitored network resources.

Overview

You can use the Microsoft Windows 2000, Windows XP, or Windows .NET Server Performance console to collect data for the present performance of your network to establish a baseline. Then, if you upgrade hardware or add new users, you can measure the network's performance again and compared it with the baseline to determine trends, identify bottlenecks, and measure capacity.

Creating a baseline for server and network activity begins with the process of identifying which server and

network resources should be systematically measured. Generally, you always want to measure at least the following four resources: memory, processor, disk, and network subsystems. Using the Performance console, you should collect data for the objects shown in the following table.

Resources and Corresponding Performance Objects to Monitor Performance

Resource	Objects to Collect
Memory	Memory, cache
Processor	Processor, system, server work queues
Disk	Logical disk, physical disk
Network	Server, network interface, network segment

These performance objects should be regularly captured for a period of time in order to collect the data needed to establish the baseline. Generally, you should append each log file collected to a master log file using relogging. Focus on periods of peak server and network activity and collect at least a week of measurements to establish your baseline.

Notes

If you want to collect disk subsystem data, first enable disk objects using the Diskperf command. Make sure you use a computer that is not being monitored to create your measurement baseline log files so that the activity of the computer doing the monitoring will not affect the data being collected.

Basic authentication

Also called cleartext or plaintext authentication, an authentication scheme that passes a user's credentials over a network in unencrypted form.

Overview

Basic authentication is defined as part of the Hypertext Transfer Protocol (HTTP) version 1 specification in RFC2617. It is not a secure authentication scheme, since anyone who can intercept network traffic and read it using a protocol analyzer can obtain the user's credentials. Although it is sometimes called cleartext authentication, Basic authentication actually encodes a

B

user's credentials using a well-known public encoding algorithm known as Uuencoding or Base64. Because the algorithm for this encoding method is so well known, however, it is easy to decode encoded text and extract a user's credentials from a Basic authentication session.

Implementation

Basic authentication is one of several authentication schemes available on Microsoft Internet Information Services (IIS) for the Microsoft Windows 2000, Windows XP, and Windows .NET Server platforms.

When a user tries to access content on a Web site hosted on IIS and the site implements Basic authentication, a dialog box appears on the user's browser asking for the user's credentials (username and password). The credentials are passed to IIS in the headers of the HTTP GET request, and are compared either to credentials in Active Directory directory service (if implemented) or to the Security Accounts Manager (SAM) database (on a workgroup server). If Active Directory is used, the user's User Principal Name (UPN) can be utilized for authentication purposes. Users who need to be able to access IIS using Basic authentication require the Log On Locally system right (although this can be changed using Active Directory Services Interface, abbreviated ADSI).

The problem with employing Basic authentication is that it is inherently insecure because of the cleartext transmission of the user's password. However, IIS does allow Basic authentication to be implemented with Secure Sockets Layer (SSL) encryption, in which case an encrypted session is first established for the user after which the user's credentials are passed to IIS in encrypted form.

The plus side of Basic authentication is that it can be performed through a firewall or proxy server (Integrated Windows authentication or Windows NTLM cannot work in this case).

Notes

Basic authentication is often used in a UNIX environment for authenticating remote HTTP users.

If you employ Basic authentication with IIS, make sure you also use the NTFS file system (NTFS) to secure access to files on your system.

basic disk

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a physical disk that can contain primary partitions, extended partitions, and logical drives.

Overview

Basic disks can be accessed by MS-DOS and legacy Windows platforms and are backward-compatible with these platforms for multiboot systems. Basic disks can also contain volumes created using Windows NT version 4 or earlier, such as spanned volumes (volume sets), striped volumes (stripe sets), mirrored volumes (mirror sets), and RAID 5 volumes (stripe sets with parity).

Basic disks are the default type of disk in Windows 2000 and Windows XP. All disks are basic disks unless you convert them to dynamic disks. Basic disks can have two kinds of partitions:

- **Primary partitions:** Basic disks support up to four primary partitions, only one of which can be marked as active.
- **Extended partitions:** Basic disks support only one extended partition, which can be further subdivided into logical drives or logical volumes.

Notes

You can create only basic volumes on basic disks. You cannot create new simple, spanned, striped, mirrored, or RAID 5 volumes on basic disks.

Basic Rate Interface ISDN (BRI-ISDN)

The slower version of Integrated Services Digital Network (ISDN) communications (the faster being Primary Rate Interface ISDN, abbreviated as PRI-ISDN).

Overview

Basic Rate Interface ISDN (BRI-ISDN, or simply BRI) communications links consist of two B channels and one D channel. The B channels carry the voice or data between the customer premises and the telco central office (CO), and the D channel (control channel) is used for establishing connections and signaling various conditions. BRI is often referred to as 2B+D because of the channels that it employs.

Since the bandwidth of each B channel is 64 kilobits per second (Kbps), the total bandwidth of BRI is twice that, or 128 Kbps. This bandwidth can be used as two separate communication links of 64 Kbps each (for example one for voice and the other for data), or it can be combined into a single 128-Kbps communication link using a technique called bonding. The bandwidth of the D channel is 16 Kbps.

Implementation

BRI connections at customer premises can be connected directly to a switch at the CO, an ISDN call controller that is linked to the CO, an ISDN Private Branch Exchange (PBX), or some other signaling and communication equipment.

If you plan to order a router or access server that supports BRI, make sure you find out from your telco of what kind of ISDN interface is used at your customer premises. The two most common interfaces are the U interface and the S/T interface, and they physically appear the same. Many ISDN access devices support both kinds of interfaces, but check to make sure first.

basic volume

A type of volume in Microsoft Windows 2000, Windows XP, and Windows .NET Server that is compatible with earlier Windows operating systems.

Overview

A basic volume can be created only on a basic disk and can be

- A volume set, mirror set, stripe set, or stripe set with parity that was created using Windows NT version 4 or earlier

bastion host

A network server that is hardened against attack from the outside world.

Overview

Bastion hosts are servers exposed to the outside world and fortified to protect them from attack by hackers. Bastion hosts usually reside on the edge of your corporate network where it connects to the Internet, and often within a specific area called the perimeter network, also known as the DMZ (demilitarized zone), which forms a kind of transition network between your corporate network and the public Internet.

There are many different kinds of bastion hosts:

- **Sacrificial hosts:** These are hosts whose security being compromised is not an issue of great importance. Examples might be a public Web server exposed only to the Internet and not to the corporate side of the perimeter network, or a test server running new applications whose security configuration is still under development, or a dummy host to distract attackers away from the real prize.
- **External service hosts:** These are servers that are primarily exposed to the Internet and may include mail servers, Web servers, and news servers. These hosts are sometimes called primary bastion hosts.
- **Internal service hosts:** These are servers that are primarily exposed to the corporate network and

B

may include name servers and logon servers. These hosts are sometimes called secondary bastion hosts.

- **Nonrouting multihomed hosts:** These are servers connected to both the internal and external networks but are configured to prevent routing between the two networks. It is essential to verify with this type of host that routing is in fact disabled.

Managing a bastion host involves several activities:

- The initial configuration of the host is important and usually involves removing unnecessary applications, disabling unnecessary services, and removing unnecessary user accounts from the host. In this sense, a bastion host can be thought of as a stripped-down server with limited but highly specific functionality. The motto “keep it simple” is a good rule of thumb when configuring a bastion host—the simpler the server’s configuration, the easier it is to monitor and troubleshoot.
- The implementation of a firewall is an essential step in securing a bastion host. The firewall may reside on the host itself or on some other server within the perimeter network, or it may be a multistage firewall residing on several hosts.
- Monitoring the bastion host once it is configured is essential to determine whether it has been attacked and whether any damage has occurred that might compromise the network. Network security is not a one-time affair but an ongoing commitment that involves auditing, performance monitoring, traffic capture and analysis, logging, and reporting.

Finally, it is essential to accept the fact that bastion hosts are likely to be compromised as new operating system and application bugs are reported and fixes issued by vendors. As a result, never put anything on a bastion host that you would mind losing or which is not available somewhere else. Accept the worst—your host will be compromised someday.

Notes

Some additional tips on deploying bastion hosts:

- Use older, slower machines for bastion hosts if possible because they are less attractive targets for attack by hackers, and, if compromised, are less useful for executing code that can be used to attack the internal network.
- Use the operating system platform you are most familiar with for your bastion hosts, as you need an intimate knowledge of the platform’s services to be able to harden them against attack.
- Place bastion hosts on a separate network from the internal corporate one, usually the DMZ or some other perimeter network.
- Make sure you physically secure the bastion hosts as well—hardening a host and then leaving it an unlocked basement room does not make sense.
- Remove all user accounts from bastion hosts except a dedicated administrator account that is protected by a strong password. Use a machine-specific administrator account rather than a domain administrator account if possible.
- Keep abreast of all releases of service packs and patches for the operating system deployed on your bastion host and apply these when required.

batch commands

A special set of commands generally found only in batch files.

Overview

Although batch files can essentially contain any commands that can be executed at the command line, a special set of batch commands enable special actions to be performed such as jumps, terminal echoing, and conditional processing.

The table on the following page lists special batch commands that are found only in batch files. These commands are all supported by Microsoft Windows 2000, Windows XP, and Windows .NET Server, but earlier versions of Windows might support only a subset of them.

Batch File Commands

<i>Command</i>	<i>Description</i>
Call	Calls one batch program from another while allowing the calling program to continue running
Echo	Toggles command-echoing on or off
Endlocal	Restores environment variables set by a Setlocal command
For	Used to run a specified command for each file in a set of files
Goto	Jumps to a specific line that is labeled in a batch file
If	Used to perform conditional processing of commands
Pause	Suspends processing of the batch file and waits for the user to respond
Rem	Used to insert remarks (comments) in a batch file for documentation purposes
Setlocal	Initiates localization of environment variables in a batch file
Shift	Used to change the position of replaceable parameters in a batch file

See Also: *batch file, Windows commands*

batch file

Also called a batch program, an ASCII file containing a series of commands.

Overview

The commands within a batch file are executed sequentially when the file is invoked. Generally, any command that can be entered at the command line can be used within a batch file as well. You can execute batch files either at the command prompt, by associating a shortcut with them and double-clicking on the shortcut, or by invoking them in a logon script or through some other script or program.

Batch files are traditionally identified using the extension .bat or .cmd. Batch files trace their origins back to MS-DOS, with the Autoexec.bat file being the best-known example. While batch files are still used by

many administrators for logon scripts, the advent of the Windows Script Host (WSH) in Microsoft Windows 98, Windows NT Option Pack, Windows 2000, Windows XP, and Windows .NET Server allows more powerful administrative scripts to now be written using higher-level scripting languages such as Microsoft Visual Basic Scripting Edition (VBScript) and JavaScript. As a consequence of the WSH, the old paradigm of batch files may finally be about to disappear.

Examples

Batch files are used primarily to simplify the execution of routine or repetitive administrative tasks such as mapping drives, synchronizing system clocks, or performing backups. For example, on a Windows NT-based network, to control the rate at which directory information is replicated between a backup domain controller (BDC) and a primary domain controller (PDC), you can create a batch file that will change the value of the ReplicationGovernor parameter on the BDC. To do this, first create a script that has the full path to this parameter in the registry along with the value you want to assign to it and then create the following simple batch file:

```
regini <Script_Name>
net stop netlogon
net start netlogon
```

Two different scripts and batch files can be created for different times of the day, and the At command can be used to schedule the execution of each batch file at the appropriate time. This illustration is especially useful if directory replication must occur over a slow wide area network (WAN) link, and you can use it to ensure that most replication traffic occurs during off hours.

bCentral

An initiative from Microsoft Corporation to help small businesses get online by providing them with subscription-based services, tips and advice, technology consultants, and other aids.

B

Overview

Microsoft bCentral is designed to help small businesses get online so they can increase sales, improve their market share, and provide better services to customers. The bCentral initiative is an integral part of Microsoft's .NET strategy of providing software as a service to consumers and businesses.

Services available from bCentral include

- Web site hosting packages that range from basic sites to full e-mail services, online advertising, e-commerce, and e-mail newsletters.
- Tools and services for advertising your online business, including search engine submission tools, opportunities to advertise on larger well-known sites, and e-mail newsletters for building customer communities.
- Back-end business support, from online services for managing your customers and tracking sales leads to secure accounting services for managing your business's finances.

In addition, bCentral services are available to any computer having a Web browser and an Internet connection, so you can manage your online business from anywhere using a laptop computer. Partnerships with companies such as Office Depot provide value-added services such as purchasing office equipment and supplies over the Internet from any location. Many bCentral services have free 30-day trial periods that allow businesses to test these services. Finally, bCentral helps you sell your company's products and services at MSN eShop and through an online auction site developed by Microsoft Corporation and FairMarket.

You can find bCentral at www.bcentral.com.

B channel

Stands for Bearer channel, a circuit-switched channel for carrying voice or data in Integrated Services Digital Network (ISDN) services.

Overview

Such channels are called Bearer channels because they "bear," or carry, the actual information being communicated between the customer premises and the telco's central office (CO). B channels are standard, bidirectional, digital telephone channels that can carry digital information at a rate of 64 kilobits per second (Kbps). Users with greater bandwidth needs can combine several B channels into larger data-carrying pipes. The two most common configurations are

- **2B+D:** Combines two B channels to form a single data pipe with a total bandwidth of 128 Kbps
- **23B+D:** Combines 23 B channels to form a high-speed data pipe equivalent to a T1 line with a total bandwidth of 1.438 megabits per second (Mbps)

Notes

B channels carry voice or data only, not signaling information. D channels carry information for establishment and control of ISDN connections.

beaconing

A technique used on token-passing networks for monitoring the status of the token-passing process.

Overview

Beaconing is used in Token Ring and Fiber Distributed Data Interface (FDDI) networks to ensure that token passing is functioning properly. On a token-passing network such as FDDI, every station is responsible for monitoring the status of the token-passing process. If a station detects that a fault has occurred, it starts placing beacons onto the ring. When the next station on the ring

detects a beacon, it in turn starts placing beacons on the ring and the first station stops transmitting them. This process will continue until the station immediately upstream of the fault location is the only station sending beacons.

Beaconing enables administrators to quickly locate the fault and repair it. Once the fault is fixed, the station emitting the beacon detects its own beacon returning to it after traveling around the ring, and the station stops beaconing.

BEEP

Stands for Blocks Extensible Exchange Protocol, an emerging framework to replace Hypertext Transfer Protocol (HTTP) for transport of Extensible Markup Language (XML)-based information over the Internet.

benchmarking

Any systematic method for performing comparative measurements of computer hardware, operating systems, and their components and subsystems.

Overview

Benchmarking began as system attempts to compare the speed and power of hardware, operating systems, and applications that had similar functions. For example, an early comparison between Microsoft Word and Corel WordPerfect might have been to compare how quickly both applications could spell-check the same 100-page document. In the early days, vendors themselves often performed benchmarking to highlight the superior performance of their products in the marketplace.

To elevate benchmarking to something more consistent and reliable, independent nonprofit organizations have been formed to benchmark certain aspects of system and application behavior. Two of these organizations have achieved a high degree of credibility in the

industry, namely Standard Performance Evaluation Corporation (SPEC) and the Transaction Processing Performance Council (TPC).

SPEC's goal is to establish a suite of standardized benchmarks for comparing the performance of computer systems. SPEC licenses its tools for use by vendors, who can publish and report the results on SPEC's Web site. An example is the SPEC CPU2000 benchmark for comparing performance of CPU subsystems, which replaces the popular, but now retired, SPEC CPU95 benchmark.

TPC's goal is to develop standard benchmarking tools and procedures for comparing transactional processing between different database products. A transaction is a form of business action performed by a computer system—for example, an online purchase or sale. Database transactions include inventory control, books, account updates, and similar procedures. TPC benchmarks such as TPC-C for Online Transactional Processing (OLTP) and TCP-W for Web-based e-commerce transactions attempt to mirror real-world transaction processing to compare the performance of database systems from different vendors.

Another popular set of benchmarks are those of media company ZDNet, which has developed its set of Winbench and Winstone benchmarks for comparison of business and consumer computer systems and peripherals.

The main difficulty with most benchmarking systems is interpreting them. While trying to mirror real-world effects, benchmarks nevertheless operate under idealized conditions in which certain variables are controlled and others are changed to study the results. The challenge continues to be to develop reliable independent benchmarks that will test significant components of complex real-world systems while maintaining fairness and vendor-neutrality.

B**BeOS**

Stands for Be Operating System, an operating system especially developed as a high-performance platform for multimedia applications.

Overview

BeOS was developed by Be, a company founded in 1991 by Jean-Louis Gassée, a former president of Apple Computer's product division. The first version of BeOS became available in 1995, and the current release is version 5.

BeOS is a preemptive multitasking operating system that incorporates pervasive multithreading in which every application has at least two threads, one for application logic and one for the user interface. BeOS also supports eight-way symmetric multiprocessing (SMP). BeOS also includes a 64-bit journaling file system that supports 18 petabytes of direct storage, protected memory, and a Portable Operating System Interface for UNIX (POSIX)-compliant subsystem.

BeOS has an object-oriented set of application programming interfaces (APIs) that are optimized for real-time digital multimedia and communication functions. Because of this, BeOS is sometimes called a "media OS" to emphasize its high-performance multimedia capabilities.

BeOS runs on Intel-based platforms and certain PowerPC-based hardware, and it includes basic Transmission Control Protocol/Internet Protocol (TCP/IP) support and services. On a PowerPC, you can even run the MacOS as a shell within the BeOS desktop interface.

A lightweight version of BeOS called BeIA (Be Internet Appliance) is also being developed for Internet appliances and similar devices.

BER

Stands for Bit Error Rate, a measurement of the reliability of a networking architecture or device.

See: Bit Error Rate (BER)

Berkeley Internet Name Domain (BIND)

A popular software tool for administering and maintaining the Domain Name System (DNS) on UNIX platforms.

Overview

Berkeley Internet Name Domain (BIND) was originally written for 4.3BSD UNIX and replaced an earlier domain naming system called JEEVES. BIND is now maintained by the Internet Software Consortium (ISC) and its current major version is BIND 9.

Because most versions of UNIX include some sort of BIND with their distributions and a majority of Internet Service Providers (ISPs) still use the UNIX platform for much of their operations, BIND is still the most popular DNS server on the Internet. BIND is also freely distributed by the ISC and is available for AIX, HP-UX, Irix, Solaris, SunOS, and other operating systems such as Linux and Windows NT.

Notes

The DNS Server services of Microsoft Windows 2000 and Windows .NET Server are Request for Comments (RFC)-compliant implementations of DNS and are fully compatible with BIND. Active Directory directory service can also use BIND as its DNS naming service, provided BIND 8.1.2 or later is used. If you choose to use BIND with Active Directory, make sure you disable name checking on your BIND server because Active Directory uses the underscore character in its SRV records and BIND name checking flags this character as an illegal character.

best effort

Used to describe network communications in which delivery of data is not guaranteed.

Overview

Routable internetworking protocols such as Internet Protocol (IP) and Internetwork Packet Exchange (IPX) use best effort delivery based on datagrams. In other words, delivery of data by these protocols is not guaranteed. The reason is that these protocols are connectionless in operation, and acknowledgements are not returned as they pass from one hop to the next across a routed internetwork.

An example where communications may fail is what is called a “black hole.” In this situation, a failed router drops packets it is supposed to forward, and the station from which the packets originated is unaware that these packets never reached their destination.

Binary Runtime Environment for Wireless (BREW)

A platform from QUALCOMM for developing applications for cellular communications systems.

Overview

Binary Runtime Environment for Wireless (BREW) was developed by QUALCOMM as an alternative to Java 2 Micro Edition (J2ME) from Sun Microsystems. Although both platforms enable downloading of applications over wireless phones, BREW has been designed from the ground up to work effectively in the cellular environment and J2ME is a general-purpose developer environment for small devices. BREW’s main disadvantage is that it was designed with QUALCOMM’s Code Division Multiple

Access (CDMA) cellular technology in mind, but J2ME is device- and technology-independent.

A number of companies have committed to building products and services that use BREW, including Wireless Knowledge and Visto Corp.

Binary Tulloch Transport Protocol (BTTP)

A draft specification for a routing protocol to save the Internet from its projected meltdown on or around April 1, 2003.

Overview

Because of the proliferation of Autonomous System Numbers (ASNs) used to identify internetworks connected to the Internet and due to the limited pool of possible ASNs, which is quickly drying up, analysts predict that no more ASNs will be available on or around April 1, 2003. At that point the Internet is expected to collapse.

A proposed solution soon to be presented to the Internet Engineering Task Force (IETF) is the Binary Tulloch Transport Protocol (BTTP). BTTP addresses the underlying issue of ASNs running out by assigning a binary flag (1=on and 0=off) to each ASN, allowing half the ASNs connected to the Internet to be temporarily revoked while the other half remain available at any given time. The protocol switches ASNs between these two states at a frequency of 1000 times per second; in other words, autonomous systems are online one millisecond and off the next, effectively reducing the size of the Internet by half at any given moment and thus giving room for several more years of expansion and growth of the Internet before the problem becomes critical again. Since the average latency for establishing Internet connections is around 20 milliseconds for wired connections (and several hundred milliseconds

B

for satellite links), this is clearly sufficient time for connections to be established with Internet hosts whose networks are rapidly switching on and off.

bindery

In Novell's NetWare version 3.x and earlier networking operating systems, the database containing network security information (such as users, groups, and rights) for a particular server.

Overview

Each NetWare 3.x server has its own bindery for controlling access to that server's file and print resources. In version 4.x and later, the bindery is replaced by the Novell Directory Services (NDS), although 4.x servers are also capable of running in bindery emulation mode.

Microsoft's optional Microsoft Windows 2000 Server service Gateway Services for NetWare (GSNW) can be used to implement gateways to resources located on NetWare file and print servers that are using bindery security. This allows Windows users to access volumes, directories, and print queues on NetWare servers without requiring NetWare client software to be installed on them. Client Services for NetWare (CSNW) can also be installed on client machines running Windows 2000 Professional and Windows XP to enable them to directly access bindery-based NetWare 2.x, 3.x, or 4.x servers that are running in bindery emulation mode.

bindings

A mechanism for linking the various components of an operating system that make network communications possible.

Overview

Bindings link together network interface card (NIC) drivers, network protocols (such as Transmission Control Protocol/Internet Protocol [TCP/IP]), and networking services (such as Workstation service). Microsoft Windows 2000, Windows XP, and Windows .NET Server let you optimize network communication by selectively enabling, disabling, and modifying the order of the bindings between these different networking components. Windows 2000, Windows XP, and Windows .NET Server support Network Driver Interface Specification (NDIS) version 5, which allows multiple protocols to be independently bound to multiple NICs.

Binding. Configuring bindings in Windows 2000.

To configure bindings for Windows 2000, choose Advanced Settings from the Advanced menu of the Network And Dial-Up Connections window, which is accessed from Control Panel. In this way bindings can

be easily enabled, disabled, or reordered. To optimize network performance, disable any unnecessary bindings on your workstations.

biometric authentication

Any authentication scheme that uses an aspect of a person's physical body or behavior to verify that person's identity.

Overview

Biometric authentication (or biometric identification) has been employed for years for entry-access control of high-security environments such as military compounds and virology laboratories, but only recently have commercial products become available for securing computer networks. Biometric authentication mechanisms take many forms, including

- Fingerprint or thumbprint identification devices
- Face-recognition systems (measure dimensions of prominent facial features)
- Iris-scanning devices (retina scanners are much more rare and expensive)
- Voice-print identification systems (usually a sound card, microphone, and software)
- Biometric trackballs and mice (measures vein patterns, creases on the palm, or density of fatty tissue using infrared lasers)

Some biometric authentication systems measure behavior patterns instead of physical features. An example is BioPassword from Net Nanny Software International, which requires a user to enter a password on a keyboard and then compares the way the user typed the password with information stored in a database.

Biometric authentication systems must be designed carefully in order for them to be truly secure. For example, a simple voice-print authentication system could be fooled by using a tape recording of the user's voice. To guard against this, these systems commonly ask the user to speak a randomly generated series of words into

the microphone, which renders such tape recordings useless.

Biometrics will probably soon make their way into the wireless arena as well. Cellular communications vendor Nokia has prototyped a biometric-enabled cell phone, which would make stealing such a phone useless. The main barrier against this development is cost—cell phones are mass-produced cheaply and even a biometric component costing \$10 per phone could break the cost model.

Another general barrier to all forms of biometric authentication systems are privacy issues regarding having digital information about your physical makeup stored on a device that could be stolen or misused. Despite these concerns, the biometrics market in 1999 was \$166 million and is rising rapidly.

Notes

When implementing biometric authentication systems, be sure to consider fallback authentication options should the biometric device fail. Costs of purchasing and deploying such systems across an enterprise may also be considerable, and help desk departments might find it more time-consuming to troubleshoot a faulty sound card of a voice-print authentication system than simply resetting a user's traditional text-based password.

Bit/Block Error Rate Tester (BERT)

A device used to troubleshoot serial lines.

Overview

A Bit/Block Error Rate Tester (BERT) is a kind of cable tester specially designed for testing serial lines. BERTs can be connected to serial ports on PCs, routers, and

B

other devices to provide a visual indication of the condition of the serial interface.

A typical BERT is a small box with a 25-pin serial connector and 25 light-emitting diodes (LEDs), one for each lead of the interface. A quick visual inspection can provide information about whether data is being reliably transmitted across the interface. You can also use jumpers to make or break specific leads to see the effect—this simulates the effect of crossed wires and can be used to detect such wires in miswired serial cables or connectors.

Bit Error Rate (BER)

A measurement of the reliability of a networking architecture or device.

Overview

Bit Error Rate (BER) is expressed in terms of probability of a bit of data being lost while being transported over a network or processed by a device. As an example, standard (10 megabits per second [Mbps]) Ethernet over copper specifies a maximum BER of 10^{-8} , which means only 1 out of every 100,000,000 (100 million) bits transported can be allowed to be lost. This is actually a worst-case scenario, however, as actual Ethernet networks generally have a BER of 10^{-11} or better, meaning that only 1 out of every 100,000,000,000 (100 billion) bits is lost. Fast Ethernet and Gigabit Ethernet (GbE) have BERs an order of magnitude smaller.

An associated measure for Ethernet reliability is Frame Loss Rate (FLR), which for Ethernet networks is typically 10^{-7} , or 1 frame lost in every 10,000,000 (10 million) frames transported. Lost frames are handled by higher-level layers of the Open Systems Interconnection (OSI) model and are ignored by the Data Link Layer.

bits per second (bps)

A unit used for measuring the speed of transmission of data on a network of computers.

Overview

Bits per second, or bps, represents the rate at which information is being sent or received. A bit is a single unit of digital information, represented by either a 1 or a 0. The total number of bits per second that can be transmitted over a network link describes the bandwidth or throughput of that link.

Because most network communication takes place at thousands or millions of bits per second, the following related units are commonly used:

- Kbps = kilobits per second (10^3 bps)
- Mbps = megabits per second (10^6 bps)
- Gbps = gigabits per second (10^9 bps)

BizTalk

An initiative from Microsoft Corporation to standardize the exchange of electronic documents between businesses.

Overview

Businesses exchange information for various reasons:

- Product invoicing and delivery
- Supply-chain management
- Electronic catalogs and ordering systems

BizTalk is designed to standardize these processes using Extensible Markup Language (XML) as a foundation for creating a standard “electronic envelope” for exchanging electronic documents between businesses.

BizTalk actually consists of four interlocking facets:

- **BizTalk Framework:** A framework for developing XML schemas to serve different sectors of business and industry. BizTalk Framework provides a set of

rules and a collection of base XML tags for building new schema for B2B e-commerce. These tags provide the “envelope” that ensures electronic documents reach their intended recipient. See the article “BizTalk Framework” later in this chapter for more information.

- **BizTalk server:** Any software that can read and process documents formatted according to the BizTalk Framework is called a BizTalk server. BizTalk servers can be third-party applications developed using any programming language and running on any operating system platform and can be designed for either front-end or back-end exchanges of B2B documents.
- **BizTalk Server 2000:** Microsoft’s own version of a BizTalk server, which runs on the Windows 2000 platform and provides orchestration of business processes and XML document exchange. BizTalk Server 2000 can transmit XML and Simple Object Access Protocol (SOAP)–based messages over a variety of transports including Hypertext Transfer Protocol (HTTP), Simple Mail Transfer Protocol (SMTP), and others.
- **BizTalk.org:** A site devoted to the support and proliferation of BizTalk.

BizTalk Framework

A specification describing the architecture of BizTalk messages.

Overview

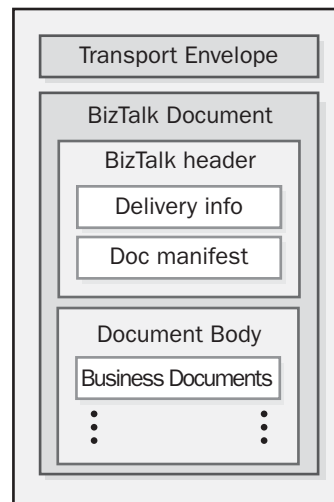

BizTalk Framework is part of the BizTalk initiative from Microsoft Corporation to facilitate the exchange of electronic documents and orchestration of business processes between trading partners, supply-chain partners, and other business partners. BizTalk Framework is designed to be the underlying document standard for

B2B e-commerce and is based on the standard Extensible Markup Language (XML) specification.

Architecture

When two businesses in a B2B relationship need to exchange information electronically, the first step is to decide on a common XML schema to use that both can understand. A schema defines the type of content being transmitted and the structure of the document containing it. Microsoft has established the site www.biztalk.org as a resource site for businesses to develop and publish BizTalk schemas for their industry sectors.

BizTalk Message

BizTalk Framework. Format for a BizTalk Message.

A BizTalk message consists of two parts: the Transport Envelope and the BizTalk Document.

The Transport Envelope specifies the transport protocol used to deliver the message. BizTalk Server 2000, Microsoft’s own implementation of a platform for building BizTalk solutions, supports a number of different transports, including

- Hypertext Transport Protocol (HTTP)
- HTTP over Secure Sockets Layer (SSL), or HTTPS

B

- Simple Mail Transfer Protocol (SMTP)
- File Transfer Protocol (FTP)
- Microsoft Message Queue Server (MSMQ)
- Application Integration Components (COM building blocks)
- Fax

The other portion of a BizTalk message, the BizTalk Document itself, consists of the following parts:

- **BizTalk Header:** Specifies the source address, destination address, subject, transmission time and date, and document manifest describing the type of document being transmitted (such as invoice, purchase order, or service request).
- **Document Body:** Contains the actual business documents formatted in XML using the agreed-upon schema. If the manifest indicates an invoice, the body describes things such as type of item sent, quantity, payment requested, and sales tax.

BizTalk Server 2000

Microsoft Corporation's platform for exchange of business documents and orchestration of business processes using the BizTalk Framework.

Overview

BizTalk Server 2000 is one of the new Microsoft Windows 2000 Server applications. BizTalk Server 2000 is used for building B2B e-commerce through using Extensible Markup Language (XML) to deliver business documents such as sales orders, invoices, and service requests. BizTalk Server 2000 can transmit both XML and Simple Object Access Protocol (SOAP)-based messages. It can use a variety of transports for accomplishing this, including Hypertext Transport Protocol (HTTP), Simple Mail Transfer Protocol (SMTP), File Transfer Protocol (FTP), and others.

Blackcomb

Microsoft Corporation's code name for its upcoming successor to the Windows .NET Server family of operating system platforms.

Overview

"Blackcomb" is planned for release sometime after the release of Windows .NET Server, which had the code name "Whistler." "Blackcomb" will be the first fully .NET version of Microsoft Windows and will be an integral platform for developing and deploying Microsoft's .NET vision of software-as-services.

At this point, little is known about "Blackcomb," but at the Windows Hardware Engineering Conference (WinHEC) in March 2001, Microsoft unveiled some of its intended features, including

- New services for Application Service Providers (ASPs) to deploy and manage .NET Web services running on Blackcomb.
- Dynamic partitioning of servers for greater reliability in mission-critical scenarios.
- Greater communications capabilities and an enhanced user interface.

Notes

Whistler and Blackcomb are two ski resorts in British Columbia, Canada, only a few hours away from Microsoft's headquarters at Redmond, Washington.

black hole

A network condition in routed internetworks where packets are dropped without any explanation to the transmitting host.

Overview

A black hole is generally caused by a router that goes down and whose absence from the network is not detected by other routers. Packets that are forwarded to the black hole are dropped—that is, they never reach their destination and give no indication to the stations sending them of the situation—therefore, the data is lost. Normally, a router will issue an “ICMP Destination Unreachable” message when it cannot forward a packet. However, with a black hole, these messages are not generated, so the transmitting host does not know that data is being permanently lost.

If static routing is being used, a black hole persists until the affected router is brought back on line or until other static routers have their routing tables reconfigured to take the downed router into account. If dynamic routing is used, other routers soon detect the presence of the black hole and adjust their routing tables accordingly to favor other paths.

Black holes can also originate when routers that are active nevertheless drop certain packets for specific reasons. An example is when the Path Maximum Transmit Unit (PMTU) is configured for a router so that it discards Internet Protocol (IP) packets that need to be fragmented in order to be forwarded. If a PMTU router is not configured to also forward indications of dropped packets to transmitting hosts (and by default they are not so configured), then the network problems they produce can be difficult to detect since some (smaller) packets get through successfully while other (larger) packets mysteriously disappear.

The reason, of course, why this condition is known as a “black hole” is its parallel with black holes in Einstein’s theory of General Relativity. Einstein’s black holes are collapsed stars that swallow everything and from which not even light can return.

block coding

An encoding scheme whereby groups of data bits are encoded into a larger number of code bits.

Overview

A variety of block codes are used for encoding transmissions for networking and telecommunications systems. Examples of some common ones include

- **4B/5B:** This packages four bits of data into five code bits and is used by 100 megabits per second (Mbps) Ethernet and Fiber Distributed Data Interface (FDDI).
- **8B/6T:** This packages eight bits of data into six ternary (base-three) code symbols and is used by 100BaseT4 Ethernet.
- **5B/6B:** This packages five bits of data into six code bits and is used by 100VG-AnyLAN.

The reasons for making the “code space” larger than the “bit space” in these encoding schemes are to allow for additional data characteristics to be included in transmissions and to make room for control signals to manage the flow of data or check for error conditions.

Blocks Extensible Exchange Protocol (BEEP)

An emerging framework to replace Hypertext Transport Protocol (HTTP) for transport of Extensible Markup Language (XML)–based information over the Internet.

Overview

Blocks Extensible Exchange Protocol (BEEP) is a proposed framework for a protocol that would run on top of Transmission Control Protocol (TCP) as an alternative to HTTP. It is designed to facilitate the exchange of

B

XML-framed information for a variety of uses, including file transfer, instant messaging (IM), and network management.

BEEP has been proposed because HTTP was not originally intended for XML data transport and performs poorly when performing this function. BEEP uses a peer-to-peer (P2P) architecture instead of the client-server one used by HTTP. In a typical scenario, BEEP first establishes a connection between two hosts on a network. The hosts alternate between client and server roles to allow two-way communications between them over a channel. Hosts can choose either to push or pull data between themselves. An advantage of BEEP is that unlike HTTP, a single BEEP connection can open multiple channels for exchange of XML data, which means, for instance, that files could be transferred through one channel while an IM chat session occurs on another.

The BEEP framework also includes a toolkit for rapid development of custom application protocols that would run on top of BEEP to efficiently handle specific types of communications tasks. In effect, BEEP would provide reusable code that would greatly facilitate the development of such special-purpose protocols.

BEEP is being presented as a draft standard to the Internet Engineering Task Force (IETF) for consideration, and the framework is outlined by RFCs 3080 and 3081. BEEP's development has been spearheaded by the company Invisible Worlds.

BEEP was formerly known by the acronym BXXP.

blue screen

In Microsoft Windows platforms, a blue screen on a user's monitor indicates that something has gone seriously wrong with the system.

Overview

In Windows 2000, Windows XP, and Windows .NET Server, blue screens are normally called stop screens. A stop screen contains complex information that qualified support technicians can use to diagnose the problem. A reboot might get the system going again, but the stop screen might reappear if the problem is not resolved. The problem causing the stop screen to appear can be either hardware-related or software-related, but the stop screen itself is generated by the operating system in response to the underlying problem.

In Windows 95 and Windows 98, the blue-colored screen normally appears when parity errors or memory violations occur. Parity errors can indicate that your system random access memory (RAM) has mismatched single inline memory modules (SIMMs) on your motherboard—for example, RAM with different speeds or a mix of parity and nonparity RAM. Also, systems from some manufacturers require special proprietary RAM in order to function. You should consult the documentation from your computer's manufacturer or your RAM's manufacturer to ensure that you have the correct type of RAM in each slot. The Windows 98 blue screen requests that you either shut down the offending application or restart your system using Ctrl+Alt+Delete.

Bluetooth

An evolving specification for short-range wireless transmission between small portable devices in a Personal Area Network (PAN).

Overview

Bluetooth is a wireless networking technology that promises to provide a simple, low-cost method of linking together cellular phones with headsets, Personal Digital Assistants (PDAs) with printers, and similar ad hoc associations between devices in a PAN. A PAN is essentially a network of portable devices carried by a user or devices within which a user comes into close proximity by movement. The vision of Bluetooth actually extends beyond personal data networking to a nirvana world of wireless devices that includes milk containers that signal refrigerators when they are almost empty, whereupon the refrigerator orders more milk using an Internet connection.

Needless to say, not everyone expects (or even wants) this brave new world to happen!

Original work on the Bluetooth specification dates back to 1994 when cellular phone manufacturer Ericsson first outlined the technology. The original intention was to provide a way to connect wireless headsets with cellular phones, but the Bluetooth specification has evolved far past this initial goal. In 1998 a consortium called the Bluetooth Special Interest Group (SIG) was created, and it published its first specification in 1999. The original members included Ericsson, its rival Nokia, and other industry leaders such as IBM, Intel Corporation, and Toshiba Corporation. This consortium has grown to include over 2000 different vendors, and the current Bluetooth specification is version 1.1.

The success of the Bluetooth SIG is based largely on the fact that companies that join must grant a royalty-free license to all other members of the alliance for any Bluetooth-related technology they develop. The SIG's main purpose is to develop specifications for real-world interoperable Bluetooth products—it is not a standards body, and the intention is that any specifications developed by the SIG will be passed on to the Institute of Electrical and Electronics Engineers (IEEE) for final standardization.

Because of the original vision of Bluetooth for small handheld devices, a consistent goal of the Bluetooth SIG has been to develop Bluetooth technology that can be implemented on a single chip. Much success has been achieved in that respect, with chip prices in large lots coming down to the \$4 range.

Architecture

Bluetooth is based on baseband FM transmission using frequencies between 2.4 and 2.4835 gigahertz (GHz) within the unlicensed 2.4-GHz Industrial, Scientific, and Medical (ISM) band. Bluetooth divides this band of frequencies into 79 separate channels, and transmission uses a frequency-hopping scheme to hop between channels randomly at a rate of 1,600 hops per second. The result is that a different frequency is used to transmit each packet of a Bluetooth transmission. The advantage of such aggressive frequency-hopping is to provide smooth operation by minimizing the effects of fading

due to reflecting obstacles and overcoming noise due to electromagnetic interference (EMI) generated by microwave ovens and other devices. Bluetooth also uses short packets and fast acknowledgments to increase reliability and employs forward error correction to reduce the effects of random noise.

Bluetooth's data transmission rate is 1 megabit per second (Mbps), but with protocol overhead the resultant practical maximum transmission rate is more like 780 kilobits per second (Kbps) or lower. Bluetooth uses a shared-media transmission scheme similar to Ethernet in which only one device in a group of connected devices can transmit at any one time, and duplex transmission is simulated through time-division multiplexing of simplex transmissions. The result is that a PAN with many Bluetooth devices will perform more poorly than one with only a few devices, but this is not considered a serious disadvantage since the specification was designed to be a lightweight one from the beginning.

Given its aim of supporting devices in PANs, Bluetooth is a low-power technology with a maximum range of transmission of 33 feet (10 meters). Bluetooth's automatic power adaptation adjusts transmission power to the minimum needed for reliable transmission in any given situation to enhance battery life in portable devices.

The Bluetooth protocol suite is centralized around the Logical Link Control and Adaptation Protocol (L2CAP). This protocol supports two data transmission modes:

- Asynchronous packet-switched communications with simplex speeds of 721 Kbps in the forward direction and 57.6 Kbps in the reverse.
- Synchronous circuit-switched communications for duplex communications over three 128 Kbps channels for a total bandwidth of 432.6 Kbps in each direction.

The Application Layer of the Bluetooth protocol suite is implemented as a series of "profiles" representing operating parameters for different kinds of uses of Bluetooth. Currently, 13 different application layer profiles have been developed under the specification, and Bluetooth systems are required only to implement a

B

core subset of these together with other profiles needed for their operation.

Other Bluetooth protocols include the Link Manager Protocol (LMP), which manages device authentication for forming new connections, and the Service Discovery Protocol (SDP), which maintains the browse list of accessible devices.

Security is built into Bluetooth at the data-link level and provides the following services:

- **Authentication:** Bluetooth has built-in device authentication, while user authentication needs to be implemented at the application level. Once a device has been authenticated, it is then considered “trusted” by all other devices in the ad hoc PAN.
- **Authorization:** This is used to control which services are accessible from which devices. For example, a Bluetooth-enabled PDA is authorized to print to a similarly enabled printer but not to a Bluetooth cell phone.
- **Encryption:** Bluetooth includes support for 128-bit encryption. In addition, the frequency-hopping transmission scheme employed by Bluetooth helps guard against eavesdropping by unauthorized users.

Implementation

Bluetooth supports concurrent connections among up to eight devices, forming what is called a piconet. Each device in a piconet is temporarily assigned a unique 3-bit MAC address for the duration of the connection. A master/slave relationship exists between one device and all other devices in the piconet for the duration of the connection. The purpose of this is for establishing clocking to synchronize devices for using the hopping sequence. In all other respects, the devices operate as peers during a connection.

Unconnected Bluetooth devices are always on in a standby mode where they listen for connection attempts every 1.28 seconds on each of 32 preassigned hopping frequencies. Once a compatible device is found, link setup and authentication is then performed using the Link Manager Protocol (LMP), which uses the link controller services built into the Bluetooth chip. Connections between Bluetooth devices can be either

point-to-point or point-to-multipoint, and groups of piconets can be joined together into larger associations called scatternets, with each piconet within a scatternet having a uniquely different hopping sequence.

Marketplace

The Bluetooth marketplace is still in its infancy, but some of the highlights are as follows:

- Bluecore, the first working Bluetooth chip, was developed by British startup Cambridge Silicon Radio. This was incorporated into the first commercial Bluetooth product, a Bluetooth-capable CompactFlash expansion card named Bluecore CF+, which was developed by California-based Socket Communications for the Microsoft Windows CE platform of portable devices. Since then other Bluetooth chips have been developed by major players such as Ericsson, Intel Corporation, and Motorola.
- RocketChips (www.rocketchips.com) has developed a vision for integrating Bluetooth onto CPU chips within PCs; in other words, a no-chip solution instead of the usual single-chip solution. If this vision is implemented, Bluetooth could become as ubiquitous as the PC.
- Red-M (www.red-m.com) has developed a complete Bluetooth solution including access server, access point, and PC cards for clients.
- Ensure Technologies has developed a Bluetooth security card that users wear and that can automatically unlock their PCs when they come near them.
- Major vendors developing Bluetooth PC cards include Toshiba, Compaq, Hewlett-Packard, and others. Motorola is producing a PC combo card with a V.90 modem and a Bluetooth chip combined.
- IBM is currently licensing Bluetooth device driver software for the Linux platform and plans similar software for Microsoft Windows platforms. IBM has also prototyped a Bluetooth-enabled PDA called WatchPad that a user wears on the wrist like an ordinary watch.

- 3Com Corporation and Extended Systems are planning on delivering a set of management tools, protocol stacks, and software development kits (SDKs) for developing Bluetooth-based solutions for the Microsoft Windows platform.
- Palm plans on integrating support for Bluetooth in its next version of the PalmOS.
- Intesil Corporation is working on dual 802.11b/Bluetooth chipsets for overcoming issues relating to interference between the two wireless networking technologies.
- Ericsson, the initial force behind Bluetooth's development, has released Bluetooth adapters for some of its cellular phone models that enable wireless connectivity between phone and headset.

The Bluetooth SIG holds a yearly conference called Unplugfest where old and new vendors of Bluetooth products meet to test interoperability between their different implementations of the specifications. Because of the specification's evolving nature, early-to-market products based on the 1.0 specification may have compatibility issues with products based upon the newer 1.1 standard.

Issues

Using the ISM band for Bluetooth communications has been problematic. The ISM band is supposedly reserved worldwide for unlicensed communications, but governments in some countries and regions have licensed portions of this band for specific uses. The problem is of special concern in Spain and France, which have only a narrow portion of the band available, and the Bluetooth specifications have been massaged to produce a special version of the specification technically able to function under these restrictions, but legal restrictions prohibit its use in these two countries to prevent the jamming of other services. The reason this is such an issue is that, due to the multiplication of different specifications, Bluetooth cellular phones will not be able to easily function throughout Europe as originally envisioned by Ericsson.

Another issue is that not only is the ISM band also used by other wireless networking technologies such as

802.11b and HomeRF, but it is also used for non-networking applications such as garage door openers, microwave ovens, cordless telephones, telco local loop systems, baby monitors, medical scanners, and various other business and consumer devices. By using an aggressive frequency-hopping scheme, Bluetooth is fairly resistant to interference from these different systems, but that very fact means that Bluetooth easily interferes with the operation of these other systems. Tests have shown, in fact, that communications over 802.11b wireless networks can be degraded and even disrupted by nearby Bluetooth devices. The result has been that large companies that rely heavily on 802.11b wireless networks have instituted policies to ban Bluetooth devices from the premises.

Besides the threat to 802.11b local area networks (LANs), Bluetooth poses dilemmas for other industries as well. The airline industry has voiced particular concern that Bluetooth devices carried by different passengers might detect each other during a flight, turn themselves on, and generate transmissions that could disrupt an aircraft's sensitive navigation equipment. The Bluetooth SIG is attempting to allay these concerns through further refinement of the specifications.

Prospects

Despite issues relating to interference with 802.11b wireless local area networks (WLANs) and whether ad hoc always-on wireless networking is desirable or even safe, Bluetooth has a great deal of momentum from industry and products are likely to be widely available soon. In addition to consumer-oriented applications for PANs and wireless public access kiosks, Bluetooth may also find some place in the enterprise as a cable-replacement technology.

Only time will tell, however, whether a Bluetooth-enabled can of beer will someday communicate with a similarly enabled refrigerator to ask it to lower the temperature for just the right taste.

Notes

The goals of Bluetooth and 802.11b are different: although 802.11b was specifically developed mainly for laptop computers as a wireless replacement for wired Ethernet LANs, Bluetooth is optimized for

B

forming short-range ad hoc networks for connecting smaller portable devices such as cell phones and PDAs. The implementations of these technologies, although confined to the same ISM frequency band, are also different: Bluetooth uses frequency-hopping, but 802.11b uses spread-spectrum transmission.

The interesting name “Bluetooth” comes from Harald Bluetooth, the Viking who in the 10th century unified Norway and Denmark.

Bluetooth also supports voice transmission that use up to three concurrent synchronous 64-Kbps voice-only channels or one channel that simultaneously supports both asynchronous data and synchronous voice transmission. The voice channels use the continuous variable-slope delta modulation-coding scheme.

A competing technology for PANs besides Bluetooth is the Infrared Data Association (IrDA) protocol, but while IrDA devices require line-of-site communication, Bluetooth devices overcome this restriction. IrDA does have certain advantages however, including much greater data transmission rates.

BNC connector

A group of connectors used for joining thinnet cable segments together and for connecting thinnet cabling to 10Base2 network cards.

Overview

BNC connectors are used on 10Base2 (thinnet) Ethernet networks and use a twist-and-lock mechanism that provides a secure connection between network cabling and components. The male connector has a center pin with a rotating ring with projections that mate with the female connector.

The various types of BNC connectors include the following:

- **BNC cable connector:** Soldered or crimped to the ends of a thinnet cable
- **BNC T-connector:** Used to connect a network interface card (NIC) to a thinnet cable segment
- **BNC barrel connector:** Used to connect two pieces of thinnet cable
- **BNC terminator:** Provides a 50-ohm termination for the free end of a thinnet cable

Notes

Several possibilities are usually suggested as to the origin of the term *BNC*:

- British Naval Connector
- Bayonet Nut Connector
- Bayonet-Neill-Concelman (probably the correct explanation since the connector was named after Neill and Concelman, its two creators)

For situations where large mechanical loads may affect cabling, a threaded form of the connector is available called TNC.

B-node

A NetBIOS name resolution method used by Microsoft Windows NT in which broadcast messages are used for name registration and resolution.

Overview

Name resolution is the process of converting the name of a host on the network into a network address (such as an Internet Protocol [IP] address). Name resolution must be performed in order to establish communication over a Windows NT network. B-node is one of four basic methods supported by Windows NT for resolving NetBIOS host names—that is, computer names—into IP addresses.

If a computer running Windows NT is configured as a B-node machine, it always uses broadcasts to resolve names of other hosts on the network. For example, if a B-node machine wants to communicate with another machine with the NetBIOS name SERVER7 (for exam-

ple, if it wants to connect to a shared resource on SERVER7), the B-node machine broadcasts a packet containing a NetBIOS name query request. If SERVER7 receives the packet, it responds by returning a frame containing its IP address. If SERVER7 is off line or fails to return a response, the B-node client will be unable to establish a connection with SERVER7.

As a name resolution method, B-node is flawed in two ways:

- Since broadcast packets are used, B-node consumes network bandwidth and can degrade overall network communication in a busy network.
- Since routers are usually configured to not forward broadcast packets, B-node clients can resolve only the NetBIOS names of hosts on the client's local subnet.

A better approach to NetBIOS name resolution on Windows NT networks is to configure clients as H-node machines and use a Windows Internet Naming Service (WINS) server. H-node is a NetBIOS name resolution method that combines B-node and P-node.

Notes

On Windows 2000 and Windows .NET Server networks, the Domain Name System (DNS) is the preferred name resolution scheme, and NETBIOS can be disabled when there are no longer any downlevel Windows NT machines left after an upgrade is complete. Note, however, that Windows 2000, Windows XP, and Windows .NET Server systems based on the Active Directory directory service must be configured with the IP address of a WINS server in order to communicate with any Windows-based systems that are not Active Directory-based, including other Windows 2000, Windows XP, and Windows .NET Server systems.

bonding

A term used to describe a variety of different technologies for aggregating multiple wide area network (WAN) links together to form a single fatter pipe.

Overview

In Integrated Services Digital Network (ISDN) and T-carrier transmission technologies, bonding provides a way of combining multiple DS0 channels from different circuits into a single, faster data transmission channel. This is accomplished using inverse multiplexing technologies together with special techniques for resolving the timing differences found among groups of different circuits.

ISDN Bonding is typically found in Basic Rate Interface ISDN (BRI-ISDN) where it is used to combine the two 64-kilobits-per-second (Kbps) B channels into a single 128-Kbps data transmission channel. Several different bonding protocols can be implemented for BRI-ISDN services, a common one being Multilink PPP (MPPP), which is used for asynchronous bonding.

Bonding must be supported by the ISDN devices at both ends of the ISDN link. Typically, one of the B channels is designated as responsible for initiating the bonding process. Many ISDN terminal adapters can override bonding when the user wants to place a regular Plain Old Telephone Service (POTS) phone call. For example, you might be using ISDN for high-speed Internet access with both B channels bonded to give you 128-Kbps (or 14-kilobyte-per-second [KBps]) access. Then, if you suddenly pick up a phone connected to the terminal adapter's POTS jack, bonding stops and the second B channel is freed up for the phone call. Once the call is complete, bonding will resume.

Another WAN technology that uses bonding is digital subscriber line (DSL). By configuring the DSL Access Multiplexer (DSLAM) at the service provider's central office (CO), hardware bonding can be implemented to link multiple DSL connections into a single high-bandwidth pipe.

An alternative to hardware bonding for DSL is customer premises equipment (CPE) bonding in which Multilink PPP is used to aggregate multiple DSL circuits at the customer premises instead of the DSLAM. This newer form of bonding has the advantage of being easier to deploy and configure than hardware bonding, which often requires costly upgrades of DSLAMs. A market example is Netopia, a DSL service provider that

B

offers bonding of up to four Internet Digital Subscriber Line (IDSL) lines.

DSL bonding has several advantages:

- Customers requiring greater bandwidth than can be afforded by a single DSL link can use bonding to deploy better than T1 services for much less the cost of a T1 line.
- Customers who are too far from their telco CO can use bonding to boost DSL carrying capacity to typical DSL speeds at twice the normal distance from customer premises to CO. For example, Netopia's IDSL bonding can provide up to 576 Kbps at distances up to 35,900 feet (10,940 meters) from the CO, which is almost double the normal DSL limiting distance of 18,000 feet (5500 meters).

boot

A term used to refer to the process of starting a computer, as in the phrase, "Please boot the computer."

Overview

The term *boot* also refers specifically to the series of steps by which a computer locates and loads the operating system once the power is turned on. This series of steps is usually referred to as the boot sequence or boot process, and it depends on both the type of operating system installed on the machine and the type of hardware platform (for example, x86 platform or Alpha platform).

The term *warm boot* refers to resetting the system or rebooting using Ctrl+Alt+Delete. The power to the system is not interrupted during a warm boot, but the boot process starts again from the beginning using the system basic input/output system (BIOS).

The term *cold boot* refers to shutting down a computer and actually turning off the power source and then turning it back on. Cold boots are sometimes necessary after installing or configuring some legacy hardware devices to ensure that the devices are properly initial-

ized. For example, if you change the configuration parameters of an internal modem, you sometimes need to cold boot your system for these changes to take effect.

boot files

Files needed to boot an operating system on a computer.

Overview

Every operating system has its own set of boot files needed to locate, load, and initialize the operating system during the boot sequence. For example, MS-DOS and Windows 3.x use the hidden files Io.sys and Msdos.sys and the file Command.com. Configuration information stored in the text files Config.sys and Autoexec.bat is also used during the process.

On Windows 95, Windows 98, and Windows Millennium Edition (Me), the files used for booting are Io.sys, Msdos.sys, and Win.com, with the files Config.sys and Autoexec.bat used optionally to support legacy hardware.

The files needed to boot Windows NT vary depending on whether the x86 or Alpha processor platform is used.

The files needed to boot Windows 2000, Windows XP, and Windows .NET Server (and Windows NT on x86) include the following:

- Boot.ini
- Bootsect.dos
- Hal.dll
- Ntdetect.com
- Ntbootdd.sys
- Ntldr
- Ntoskrnl.exe

The Windows 2000, Windows XP, and Windows .NET Server boot process also makes use of other files, including device drivers and the system hive.

Boot.ini

A file used to create the boot loader menu in Windows 2000, Windows XP, and Windows .NET Server.

Overview

Boot.ini is a hidden, read-only text file on the root of the system partition of a Microsoft Windows 2000, Windows XP, or Windows .NET Server machine. The boot loader menu is used on dual-boot and multiboot systems to select which operating system (Windows 2000 or some other operating system) to boot. The Boot.ini file creates this menu, which normally is only displayed if more than one operating system is installed on the machine.

Examples

A typical Boot.ini file for a default Windows 2000 installation might look like this:

```
[boot loader]
timeout=30
default=multi(0)disk(0)rdisk(0)partition(1)\
WINNT
[operating systems]
multi(0)disk(0)rdisk(0)partition(1)\
WINNT="Microsoft Windows 2000 Professional"
/fastdetect
```

You can see a close correspondence between the appearance of the Boot.ini file and the boot loader menu, which the Ntldr program creates during the Windows NT boot sequence.

A Boot.ini file for a dual-boot system configured to boot to either Windows 2000 or Windows 98 usually looks like this:

```
[boot loader]
timeout=30
default=multi(0)disk(0)rdisk(0)partition(1)\
WINNT
[operating systems]
multi(0)disk(0)rdisk(0)partition(1)\
WINNT="Microsoft Windows 2000 Professional"
/fastdetect
C:\="Microsoft Windows"
```

The last line of the file is the same for booting to any MS-DOS–based operating system, including Windows 95, Windows 98, and Windows Millennium Edition (Me).

boot loader menu

A menu that appears when you boot a Microsoft Windows 2000, Windows XP, or Windows .NET Server computer configured for dual-boot or multiboot operation with other operating systems.

Overview

The boot loader menu appears during the boot loader phase of Windows NT startup, and it is displayed by the Windows 2000, Windows XP, and Windows .NET Server loader program called Ntldr. The boot loader menu allows you to select the particular operating system you want to run on a dual-boot or multiboot system and to use optional boot-time switches for booting Windows 2000, Windows XP, and Windows .NET Server in various enhanced ways or for troubleshooting purposes. The table summarizes some of the more commonly used boot-time switches used in Boot.ini.

Some Common Boot-Time Switches Used in Boot.ini

<i>Switch</i>	<i>Description</i>
/3GB	Used only with Windows 2000 Advanced Server to increase user address space from 2 gigabytes (GB) to 3 GB
/basevideo	Starts Windows 2000 using generic Video Graphics Adapter (VGA) video
/bootlog	Creates a log, called Ntbtlog.txt, of steps in the boot process
/fastdetect	Skips enumeration of serial and parallel devices during the boot process (included by default)
/numproc=	Specifies the number of CPUs to use on a symmetric multiprocessing (SMP) system
/sos	Lists the device drivers marked to load at boot time and displays other information

B

Notes

The boot loader menu is created by the Boot.ini file. This file can be edited using a text editor such as Notepad, but this should be done with care as mistakes could render your system unbootable.

BOOTP

Stands for bootstrap protocol, a Transmission Control Protocol/Internet Protocol (TCP/IP) protocol and service that allows diskless workstations to obtain their IP address, other TCP/IP configuration information, and their boot image file from a bootstrap protocol (BOOTP) server.

See: bootstrap protocol (BOOTP)

boot partition

The partition of a disk on which Microsoft Windows 2000, Windows XP, or Windows .NET Server installs its core operating system files.

Overview

The core operating system files for Windows 2000, Windows XP, and Windows .NET Server are typically stored in \Winnt and its subdirectories. The \Winnt directory and its system files are located on what is referred to as the boot partition (by a strange choice of terminology, the boot files in Windows 2000, Windows XP, and Windows .NET Server are stored on the system partition).

The choice of which partition is to be the boot partition is made during installation of Windows 2000, Windows XP, and Windows .NET Server and cannot be changed afterward. An important consideration when installing Windows 2000, Windows XP, and Windows .NET Server is designating a boot partition that has sufficient free space to contain the various operating system files together with all the optional and future components such as device drivers.

Notes

The boot partition can be the same as or different from the system partition.

boot process

The series of steps that occurs when an operating system boots on a machine.

Overview

Each operating system has its own particular boot sequence and uses its own specific set of boot files. Knowledge of the boot sequence for a particular operating system can aid in troubleshooting problems booting a machine on which that operating system is installed. For example, from messages displayed during the boot process, a technician can often determine whether a particular boot file is missing or corrupt.

The following is a brief summary of the boot sequence for the Microsoft Windows 2000 operating system (the Windows XP and Windows .NET Server boot sequences are similar). Note that the actual boot process involves more than 100 different steps and that this description gives only an overview of the process.

- **Preboot:** The boot process can take place only because during installation Windows 2000 Setup writes boot code (a short series of executable instructions) on the master boot record (MBR) located on the first sector of the first hard disk. The MBR also contains the partition table identifying which partition is the active (bootable) partition that contains the operating system boot files. Setup also creates a file called Boot.ini that is used to display a boot loader menu on systems configured for dual-booting or multibooting to Windows 2000 and other operating systems.
- **Ntldr:** When a Windows 2000 system is powered on, the basic input/output system (BIOS) reads the MBR into memory and transfers control to the MBR, which then finds, loads, and executes Ntldr, a key Windows 2000 executable boot file. When

Ntldr starts, the processor is still running in 16-bit real mode, and the first thing Ntldr does is switch the processor to 32-bit protected mode. Ntldr then creates page tables and enables paging. At this point, if the boot or system drive is on a Small Computer System Interface (SCSI) drive, Ntldr loads Ntbootdd.sys, which functions as a device driver for the drive. Once this stage is passed, Ntldr clears the screen and if the system is configured for multiboot operation, it then displays the boot loader menu generated using Boot.ini (this menu is not displayed if the only operating system installed is Windows 2000 itself). Assuming single-boot mode, Ntldr then locates the system directory (usually \Winnt), clears the screen again, displays the “Starting Windows” progress bar, and begins loading additional files including the kernel (Ntoskrnl.exe); and the hardware abstraction layer, or HAL (Hal.dll), reads the SYSTEM hive to determine which other device drivers to load, loads and initializes the file system and device drivers needed, and various other tasks. Then Ntldr calls Ntoskrnl.exe for the next stage of the boot process.

- **Ntoskrnl.exe:** The operating system kernel Ntoskrnl.exe performs a two-phase initialization that consists of more than 30 different steps that are too involved to explain here. As these steps are performed, the Starting Windows progress bar moves toward 100 percent, at which time the Session Manager subsystem (Smss) is initialized.
- **Smss:** The role of Smss is to create the user-mode environment that provides the graphical user interface (GUI) by which the user completes the boot process and accesses the system. Smss performs a whole series of steps ending in its main thread waiting for the Winlogon process to generate the logon dialog box.
- **Logon:** Once the logon dialog box is generated, the user enters the necessary credentials, is authenticated, and the desktop user interface appears. The boot process is now complete.

Bootsect.dos

A boot file in Microsoft Windows 2000, Windows XP, and Windows .NET Server used to support dual-boot scenarios with MS-DOS–based operating systems such as Windows Millennium Edition (Me).

Overview

When the boot loader menu appears during the boot process on a dual-boot Windows 2000, Windows XP, or Windows .NET Server machine, the user selects the operating system to boot. If an MS-DOS–based operating system such as Windows 95, Windows 98, or Windows Me is selected, the Ntldr program immediately switches the processor back to 16-bit real mode and then loads Bootsect.dos and turns control of the boot process over to it. Bootsect.dos then continues with an MS-DOS-specific boot process leading to initialization of the selected operating system.

Bootsect.dos contains the location of the partition boot sector that existed on the partition prior to the installation of Windows 2000, Windows XP, or Windows .NET Server. Thus, Bootsect.dos enables the system to locate and load the alternate operating system. Bootsect.dos is not loaded during a normal boot of the Windows 2000, Windows XP, or Windows .NET Server operating system.

bootstrap protocol (BOOTP)

A Transmission Control Protocol/Internet Protocol (TCP/IP) protocol and service that allows diskless workstations to obtain their IP address, other TCP/IP configuration information, and their boot image file from a bootstrap protocol (BOOTP) server.

Overview

The network interface card (NIC) on these diskless workstations contains a programmable read-only memory (PROM) chip containing code necessary to initialize the client.

When a bootstrap protocol (BOOTP) client is started, it has no IP address, so it broadcasts a message containing its MAC address onto the network. This message is called a “BOOTP request,” and it is picked up by the

B

BOOTP server, which replies to the client with the following information that the client needs:

- The client's IP address, subnet mask, and default gateway address
- The IP address and host name of the BOOTP server
- The IP address of the server that has the boot image, which the client needs to load its operating system

When the client receives this information from the BOOTP server, it configures and initializes its TCP/IP protocol stack, and then connects to the server on which the boot image is shared. The client loads the boot image and uses this information to load and start its operating system.

BOOTP is defined in RFCs 951 and 1084. The Dynamic Host Configuration Protocol (DHCP) was developed as an extension of BOOTP.

Notes

The term *bootstrap protocol* (or *boot protocol*) comes from the idea of lifting yourself up by your own bootstraps—something that is obviously difficult to do. In other words, how does a client machine start up when it initially has neither an IP address nor an operating system? BOOTP makes this difficult task possible.

Most UNIX servers support diskless workstations using the BOOTP protocol. BOOTP is implemented on UNIX servers using the `bootpd` daemon. Certain aspects of BOOTP are supported by Microsoft Windows 2000, Windows XP, and Windows .NET Server, but the protocol is rarely used in Windows networks.

boot volume

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, the volume that has the operating system files.

Overview

The boot volume can be the same as or different from the system volume, and it can be formatted in either NTFS file system (NTFS) or file allocation table (FAT). The term *volume* indicates that we are referring here to dynamic storage, which enables volumes to be created and managed. By contrast, basic storage enables the creation and management of partitions instead.

Border Gateway Protocol (BGP)

An exterior gateway protocol (EGP) used on the Internet to provide loop-free routing between different autonomous systems (ASs).

Overview

The Internet consists of large, independently administered networks called ASs connected by routers to form a single, enormous internetwork. ASs themselves are smaller internetworks and contain routers that exchange routing information with each other using various interior gateway protocols (IGPs) such as Routing Information Protocol (RIP) and Interior Gateway Routing Protocol (IGRP). These IGPs do not scale well enough to handle exchange of routing information between the border routers that join various ASs together, however, and for such purposes exterior gateway protocols (EGPs) are used, the de facto standard EGP for the Internet being the Border Gateway Protocol (BGP).

Like RIP and IGRP, BGP is based on the distance vector routing algorithm (or more specifically on a variant called path-vector), which enables groups of routers to share their routing information in a highly efficient and scalable manner. The routing information BGP exchanges between boundary routers is called Network Layer Reachability Information (NLRI), and specifies which other AS's data can be forwarded to from the local AS and the most efficient routes (best path) for doing this. BGP also can ensure against routing loops occurring.

BGP was developed in 1982 as the successor to EGP and was formalized in RFCs 827 and 904. Since then it has gone through several versions, with the current version being BGP 4, specified by RFC 1771. BGP 4 includes a number of enhancements over earlier versions, including support for

- Route and path aggregation
- Route, path, and community filtering
- Routing policies
- Advertising Internet Protocol (IP) prefixes
- Classless Interdomain Routing (CIDR)

Architecture

BGP is a connection-oriented protocol that runs on top of Transmission Control Protocol (TCP) to provide reliable transport of routing updates. TCP port 179 is used for forming connections between BGP-enabled routers, and incremental updates to routing tables only are transmitted, which makes BGP efficient in terms of bandwidth utilization (other distance-vector routing protocols exchange entire routing tables at regular intervals, which makes them scale poorly to internetworks the size of the Internet).

To use BGP, your internetwork must first be assigned an Autonomous System Number (ASN). You can get one by contacting your regional Internet registry, such as the American Registry for Internet Numbers (ARIN) for North and South America, Reseaux IP Européens (RIPE) for Europe, or the Asian-Pacific Network Information Center (APNIC) for Asia. ASNs for public internetworks are assigned from the range 1 through 64511.

BGP-speaking routers within an AS establish peering relationships with each other to form a loop-free routing mesh. The first update between two peers includes all known routes on the network, while succeeding updates are incremental.

Implementation

BGP needs to be implemented only in very large internetworks. When smaller internetworks using IGRP

grow to the point that IGRP performs poorly, BGP can be used to partition the internetwork into two autonomous systems for better routing performance.

Another situation where you might implement BGP is if your corporate internetwork is multihomed, that is, has several dedicated connections to the Internet using different Internet service providers (ISPs). In this case, you can use BGP to balance the load between the Internet connections and provide redundancy.

Finally, if your corporate internetwork is being used as a transit network to connect other networks to the Internet, you need to employ BGP.

If you plan to implement BGP, make sure your router is powerful enough to handle it, especially if your internetwork will be directly connected to a regional ISP's network.

Notes

There are actually two flavors of BGP, though this distinction is not widely used in the literature:

- **EBGP (Exterior BGP):** The form used for communication between different ASs for BGP-enabled routers. This is also simply known as BGP and is the version described in this article.
- **IBGP (Interior BGP):** The form used for communication within an AS for BGP-enabled routers.

border router

A router that connects two different autonomous systems (ASs).

Overview

The Internet consists of a collection of thousands of different independently administered large internetworks called ASs. Border routers are high-speed backbone routers that connect these different internetworks.

Border router. Using a border router to connect two autonomous systems.

Border routers use the Border Gateway Protocol (BGP) as the routing protocol for exchanging route information between them. Since the routing tables for border routers are large and rapidly growing as the Internet

itself expands and evolves, border routers need to be high-performance, with at least 64 kilobytes (KB) of memory to hold these routing tables. Without these border routers and BGP, the Internet would be limited to a much smaller size than it is.

bottleneck

A situation that occurs when computer and network systems and components are unable to meet the demand placed upon them by real-world situations.

Overview

A bottleneck is essentially the particular network component or server subsystem that is causing the problem. For example, if users on a Microsoft Windows 2000–based network are complaining that it takes too long to log on when they arrive at the office in the morning, the bottleneck and its potential resolution might be

- Not enough domain controllers to handle logon requests (A solution: add more domain controllers)
- The domain controller does not have enough memory to process large numbers of simultaneous logons (A solution: add more random access memory [RAM])
- Network bandwidth is saturated in the morning with directory replication traffic (A solution: reschedule directory replication or upgrade to 100 megabits per second (Mbps) Ethernet)

The etymological reason for describing each of the above situations as a “bottleneck” is that a bottle’s thinnest point is its neck and hence the neck controls the flow of liquid should the bottle be inverted. In the same way, the performance of an application running on a computer system can be limited by the amount of physical memory, read/write speed of the disk subsystem, throughput of the network interface card, speed of the CPU, and other parameters—any of these components (or several of them) could be a bottleneck that prevents the application from performing as desired. Or more

generally, the performance of a browser accessing Web content on a corporate Intranet could be affected by overworked name servers for Domain Name System (DNS) name resolution, an insufficient number of domain controllers to handle authentication requests, slow or faulty routers joining subnets within an inter-network, misconfigured firewalls, and a host of other issues that could represent bottlenecks.

Notes

Troubleshooting bottlenecks is the science (sometimes the art) of identifying, isolating, and correcting issues that limit application performance. Valuable tools for ferreting out bottlenecks in Windows 2000–, Windows XP–, and Windows .NET Server–based networks are the Performance console, one of the administrative tools in Windows 2000, Windows XP, and Windows .NET Server, and Task Manager. For system performance, there are four main types of bottlenecks:

- **Processor bottlenecks:** If a CPU's utilization is constantly running near 100 percent when a certain application is running, it might indicate a processor bottleneck, in which case the application is said to be processor-bound. Upgrading to a faster processor or adding a second processor to a multiprocessor-capable motherboard might correct the problem.
- **Memory bottlenecks:** These bottlenecks arise when the system has insufficient RAM, which generally results in excessive paging and overall poor performance. Adding more RAM is often the simplest and cheapest solution to improve performance of most computer systems.
- **Disk bottlenecks:** Sometimes the hard disk subsystem cannot keep up with read/write requests generated by an application. In such a case the application is said to be disk-bound, and upgrading to a faster disk subsystem, implementing disk striping, or using a storage area network (SAN) can improve performance. Often, however, when disk activity is consistently too high, this simply indicates excessive paging caused by insufficient RAM. In this situation, what appears at first to be a disk bottleneck is actually one of memory instead.

- **Network bottleneck:** With today's Gigabit Ethernet (GbE) networks, older servers simply cannot pipe data fast enough from their system bus into their GbE network cards to get it onto the network. What seems to be a network bottleneck here is really caused by the inadequate speed of the system bus, and upgrading the motherboard is the only real option. True network bottlenecks are more difficult to find and may result from misconfigured routers, network cards running in promiscuous mode, excessive broadcast overhead from using too many protocols on the network, poor planning of network topologies, and many other issues.

bounce

An effect that happens to signals on a bus topology network when the ends of the bus are improperly terminated or unterminated.

Overview

A signal that is placed on a bus that is unterminated will continue to reflect from the end of the bus until that signal is attenuated by the impedance of the cable. Another situation that can cause signals to bounce is a break in the cable, which essentially creates two unterminated ends for the two segments.

The effect of signal bounce on baseband networks such as Ethernet is serious, since the transceivers on the network interface cards (NICs) attached to the bus interpret the problem as a collision and stop transmitting. This collision occurs because the signal is colliding with its own reflection. Once the proper termination is applied to the bus, network communication can resume.

bps

Stands for bits per second, a unit used for measuring the speed of transmission of data on a network of computers.

See: bits per second (bps)

B

breakout box

A troubleshooting tool used to determine the wiring of an RS-232 interface on a networking device or computer.

Overview

A breakout box can be inserted between two RS-232 devices to determine which wires are active. Breakout boxes are useful in troubleshooting RS-232 connection problems resulting from a manufacturer's device not using standard pinning.

Breakout boxes are specific examples of a more general category of network testing equipment called "status monitors." Status monitors are available for testing a variety of serial interfaces, including RS-232, RS-449, V.35, and X.21. They generally come with a variety of connectors and are quick and easy to use for isolating problems with serial transmission connections in networking, telecommunications, and industrial settings.

BREW

Stands for Binary Runtime Environment for Wireless, a platform from QUALCOMM for developing applications for cellular communications systems.

See: Binary Runtime Environment for Wireless (BREW)

bridge

A networking component used either to extend or to segment networks.

Overview

Bridges work at the data-link layer of the Open Systems Interconnection (OSI) model of networking. They can be used to

- Segment networks into smaller collision domains
- Join dissimilar media such as unshielded twisted-pair (UTP) cabling and fiber-optic cabling
- Join together different network architectures such as Token Ring and Ethernet (called a translation bridge)

Local Bridge

Remote Bridge

Wireless Bridge

Bridge. The three basic types of bridge.

Bridges regenerate signals but do not perform any protocol conversion, so the same networking protocol (such as Transmission Control Protocol/Internet Protocol [TCP/IP]) must be running on both network segments connected to the bridge. Bridges can also support Simple Network Management Protocol (SNMP), and they can have other diagnostic features.

Bridges come in three basic types:

- **Local bridges:** Directly connect local area networks (LANs) (called a transparent bridge for Ethernet networks and a source-routed bridge for Token Ring networks)
- **Remote bridges:** Can be used to create a wide area network (WAN) link between two LANs
- **Wireless bridges:** Can be used to join LANs or connect remote stations to LANs without wiring between them

Architecture

Bridges operate by sensing the source MAC addresses of the transmitting nodes on the network and automatically building an internal routing table. This table is used to determine which connected segment to route packets to, and it provides the filtering capability that bridges are known for.

If the bridge knows which segment a packet is intended for, it forwards the packet directly to that segment. If the bridge does not recognize the packet's destination address, it forwards the packet to all connected segments except the one it originated on. And if the destination address is in the same segment as the source address, the bridge drops the packet.

Bridges also forward broadcast packets to all segments except the originating one.

Advantages and Disadvantages

Bridges are less expensive than routers and can easily be used to add more stations to a network. They are transparent to high-level protocols and can even be used with nonroutable protocols that routers cannot handle.

Bridges have the disadvantages, however, of increasing the chance of broadcast storms occurring on a network and are not as efficient in larger networks as routers are.

Implementation

Use bridges to reduce network congestion and improve performance by segmenting busy Ethernet networks into smaller collision domains. You can also use bridges to connect segments more efficiently than repeaters and to join dissimilar networks such as Ethernet and Token Ring. Remote bridges can be used to create WAN links.

A poorly placed bridge can actually worsen network performance. For example, if you use a bridge to divide users who belong to the same department and frequently communicate with one another over the network, this might actually slow down communication among users by creating a bottleneck. It is better to use bridges to join together separate departmental LANs on which intradepartmental traffic is greater than interdepartmental traffic.

When using bridges to connect networks, make sure that only one path leads to any destination node on the network; otherwise, frames could become locked in loops and circle the network endlessly, causing a network storm.

Notes

Switches and bridges function similarly, but although switches can have many ports, bridges only have two.

bridgehead server

A server that acts as an endpoint of communications with another site.

Overview

In Microsoft terminology, bridgehead servers occur in several contexts. For example, in Microsoft Exchange Server, a bridgehead server in one site is responsible for routing messages through a connector to a similar server in a different site. More generally, in Microsoft Windows 2000 and Windows .NET Server, a bridgehead server is a domain controller that replicates Active Directory directory service information with domain controllers in other sites. The first domain controller in each site assumes the role of Inter-Site Topology Generator and determines which domain controllers in the site will be selected as bridgehead servers.

BRI-ISDN

Stands for Basic Rate Interface ISDN, the slower version of Integrated Services Digital Network (ISDN) communications (the faster being Primary Rate Interface [PRI]-ISDN).

See: Basic Rate Interface ISDN (BRI-ISDN)

broadband

A signaling technology that sends signals simultaneously over a range of different frequencies as electromagnetic waves. The opposite of baseband.

See: broadband transmission

B

broadband Internet access

Generally refers to various technologies such as digital subscriber line (DSL) and cable modems that provide high-speed Internet access for residential and business customers.

Overview

The growth and evolution of the Internet and World Wide Web over the last 10 years has seen simple text-based Web pages become replaced with media-rich content that includes graphic files, sound clips, Shock-wave animations, and streaming media. In addition text-based Simple Mail Transfer Protocol (SMTP) e-mail has become heavy with large attachments including Microsoft Word files, spreadsheets, images, and other content. These changes in content forms require high-bandwidth Internet connections, and traditional dial-up modem connections (even 56K) feel inadequate to many users.

As a result, the broadband Internet access market has taken off in the last couple of years, with widespread deployment of cable modem and DSL connections now in the millions. In addition, for remote locations, companies such as StarBand Communications and Digistar provide satellite-based broadband Internet access with download speeds in the 2-megabit-per-second (Mbps) range (for more on satellite-based broadband, see the article “broadband wireless communications” elsewhere in this chapter).

The two most commonly deployed broadband Internet access solutions are cable modems and variants of DSL. Cable modems are a low-cost solution that is easier to deploy than DSL, but they are generally only available in residential markets where the cabling infrastructure has already been widely deployed. DSL is a more complex solution offered by telcos but has the advantage that connections are dedicated rather than shared: a DSL connection offers guaranteed bandwidth, while the effective bandwidth for a cable modem connection depends on the number of users to which it is deployed in a given area (cable modem users are essentially connected in a LAN and so share the available bandwidth of the LAN).

Speed is the main benefit of various broadband Internet access technologies, and a comparison is useful:

- **Copper DSL:** Running various flavors of DSL such as Asymmetric Digital Subscriber Line (ADSL) and Symmetric Digital Subscriber Line (SDSL) over the copper local loop to subscribers can offer speeds of up to 8 Mbps, but download speeds of 1 or 2 Mbps are more common (upload speeds may be less).
- **Fiber DSL:** By running fiber to the curb, significantly higher DSL speeds of up to 60 Mbps or higher can be achieved, but the cost is high due to the need to deploy a new fiber infrastructure. This is an attractive solution for businesses, however, especially where telcos are rolling out such infrastructures.
- **Cable modem:** Typical cable modem speeds are between 2 and 6 Mbps, but effective speeds may be much less for users due to the shared-bandwidth nature of this solution.

Uses

In addition to providing the ability to surf the Web at high speeds or send Christmas card images through e-mail, broadband Internet access is seen by increasing numbers of companies as an idea solution for supporting the remote workforce of home-based telecommuters. By using a cable modem or DSL connection and setting up a Virtual Private Network (VPN) connection using Microsoft Windows 2000, Windows XP, and Windows .NET Server, or some other platform, employees can work from home across secure connections to their company intranet.

Large companies that choose DSL or other broadband solutions as replacements for or backups to existing leased-line wide area network (WAN) links need to consider things such as service level agreements (SLAs), Quality of Service (QoS) guarantees (usually nonexistent for DSL), the number of Internet Protocol (IP) addresses that can be provided with the connection (usually under 150 for DSL), deployment times (usually weeks, but sometimes months), and business pricing (which is significantly more than residential pricing).

Advantages and Disadvantages

One important limitation of DSL as a broadband Internet access solution is that it is only viable within a small distance from the telco's central office (CO). This distance is typically about 18,000 feet (5500 meters) for the most popular implementation of DSL; that is, ADSL. Cable modem provisioning does not suffer from this distance limitation, but its deployment is limited to areas where the necessary cabling infrastructure is already present, which excludes most business and industrial parks.

Cable modems also have the additional advantage of being simpler to implement than DSL, which often requires professional installation services. On the other hand, DSL is intrinsically more secure than cable modems since DSL connections are dedicated—it is just your customer premises and the DSL provider on the network. With cable modems, all users in a given service area are on a shared LAN, and if your connection is not secured using a firewall, then other users in your neighborhood may be able to view and access shared files on your system.

Marketplace

Copper DSL is available from most telcos and carriers, including Sprint Corporation, Covad Communications Company, the various “baby Bells,” and many others. Fiber DSL is being piloted by Pacific Bell Telephone Company and others.

Most cable companies provide cable modem access now, with AT&T being a major player in this market.

Prospects

While broadband Internet access services are becoming more and more widely deployed in the United States, the marketplace tends to be fractured, and solutions and equipment from one vendor often have interoperability issues with those from other vendors. This is especially the case with broadband wireless technologies.

One country that is taking a more aggressive approach to broadband is Japan. While the Japanese economy largely missed out on the narrowband Internet and PC revolution of the 1990s, the country is making strong efforts to become the world leader in implementing

broadband Internet technologies, with companies such as Sony taking the lead.

broadband ISDN (B-ISDN)

The broadband transmission counterpart of Integrated Services Digital Network (ISDN).

Overview

Broadband ISDN (B-ISDN) encompasses a set of International Telecommunication Union (ITU) standards and services designed to provide an integrated digital network for audio, video, and data transmission. Instead of using the copper media used in ordinary ISDN, broadband ISDN uses fiber-optic and radio media.

Broadband ISDN is designed to use the cell-switching transport technology of Asynchronous Transfer Mode (ATM) together with the underlying physical transport mechanisms of Synchronous Optical Network (SONET). Broadband ISDN standards and technologies were intended to provide high-speed digital connectivity for homes and businesses, but the technology was never widely deployed and has been superseded by Digital Subscriber Line (DSL) and other high-speed telco services.

See Also: *Digital Subscriber Line (DSL)*

broadband transmission

A signaling technology that sends signals simultaneously over a range of different frequencies as electromagnetic waves. The opposite of baseband transmission.

Overview

Broadband transmissions are divided into multiple bands or channels by multiplexers using a multiplexing scheme such as frequency-division multiplexing (FDM). Each channel has a carrier frequency that is modulated to carry the signal from a given source. At the receiving station, multiplexers separate the various signals. Guard bands are used to prevent interference among channels.

B

Broadband signals are unidirectional—traveling in only one direction at a time—so a broadband system can generally either transmit or receive but cannot do both simultaneously. Broadband signals can be regenerated using amplifiers in order to travel longer distances before becoming attenuated.

Uses

Broadband transmission is typically used for environments in which video, audio, and data need to be transmitted simultaneously. Cable television systems are based on broadband transmission technologies, as are satellite-based television services. Examples of broadband services in the computer networking arena include T-carrier services, Asynchronous Transfer Mode (ATM), and the various flavors of Digital Subscriber Line (DSL).

broadband wireless communications

Generally refers to high-speed wireless communications systems where data rates are approximately 1 megabit per second (Mbps) or higher.

Overview

Broadband wireless (or wireless broadband) is an emerging high-speed communications technology that is being largely driven by the Internet access market. Broadband wireless systems achieve data rates comparable to Digital Subscriber Line (DSL) or cable modems and can be used in environments where these technologies are unavailable or difficult to deploy, such as isolated rural areas. And like DSL and similar technologies, broadband wireless is an always-on solution that provides fast access to the Internet and can be used in other corporate wide area network (WAN) scenarios as well.

Broadband wireless basically comes in three forms: fixed wireless, mobile wireless, and satellite-based.

Fixed broadband wireless is a technology that is gaining significant market share at all levels, from small

businesses to the enterprise. In a typical fixed wireless scenario, a business requiring high-speed Internet access or a WAN connection deploys a broadband radio transmitter/receiver with a fixed unidirectional dish or horn antenna pointed toward the service provider's antenna. A clear line of sight is required between the customer premises antenna and the provider's antenna, which generally means customers deploy their antenna on their rooftop and providers deploy antennas on high towers, skyscrapers, or nearby mountains. Fixed wireless broadband can be based on various different technologies including Local Multipoint Distribution System (LMDS), Multichannel Multipoint Distribution System (MMDS), and others. Fixed broadband wireless communications systems are based on spread-spectrum communications technologies and may use frequencies from the Industrial, Scientific, and Medical (ISM) band's 2.5 GHz range up to millimeter wavelengths in the 66 gigahertz (GHz) range. Dedicated point-to-point microwave links can offer data transmission speeds of 10 Mbps or higher, but speeds of 1 or 2 Mbps are more common.

Mobile broadband wireless solutions are still in planning stages in most countries and regions, with Europe and Asia in the lead with planned rollouts of 3G cellular technologies such as Wideband Code Division Multiple Access (WCDMA) and Universal Mobile Telecommunication System (UMTS). Nevertheless, widespread deployment of these technologies probably will not happen until 2005 or later.

Mobile broadband services are also expected to provide significantly slower speeds than fixed solutions. For example a WCDMA system that provides 2 Mbps for fixed transmission can only support 384 Kbps for mobile (walking) transmission when handoffs are required, and may go as low as 144 Kbps for highway travel.

Satellite-based broadband wireless solutions generally offer speeds of around 2 Mbps, are easy to deploy, and are rapidly becoming more widely available. An in-depth discussion of how this technology works can be found in the article "satellite networking" elsewhere in this book.

Uses

Companies may implement broadband wireless in a variety of scenarios:

- Fixed broadband wireless is often used for providing high-speed Internet access, for streaming video broadcasting from remote locations, and for backup links to leased-lines used for WAN links between branch offices.
- Mobile broadband wireless, when deployed, will probably be used for high-speed Internet access for cell phones, Personal Digital Assistants (PDAs), and other hand-held information appliances.
- Satellite-based broadband wireless is primarily intended to replace enterprise WAN links and for providing high-speed Internet access in remote locations.

Advantages and Disadvantages

A primary advantage of broadband wireless over competing wired broadband technologies such as DSL or cable modems is their ease of setup and the speed at which they can be deployed. Industry reports indicate that DSL services sometimes take weeks to set up, but fixed broadband wireless solutions typically take only a day or two. In the rapidly evolving Internet economy where time-to-market is critical for new startups, deployment speed is a factor that has influenced many new companies in adopting broadband wireless solutions. In addition, many large companies are turning to broadband wireless to replace or provide backup for expensive leased lines such as T1 or E1 at a fraction of the cost of these lines. Some broadband wireless carriers are also looking at providing value-added services such as Voice over IP (VoIP) in the near future as part of their integrated package of services. Broadband wireless systems are also relatively secure because most are based on spread-spectrum wireless communications technologies, which means that signals are scrambled across a large number of frequencies, making it difficult to eavesdrop (a firewall is nevertheless recommended when implementing broadband wireless as this is an always-on solution). Finally, broadband wireless is often the only solution for customers in remote areas requiring broadband Internet access or WAN links.

Besides the line-of-site limitation, broadband wireless does have other disadvantages that need to be considered before deployment. High-frequency broadband wireless platforms such as LMDS are more easily influenced by environmental factors such as weather than systems that use the low-frequency ISM or other low-frequency bands, and that can be a consideration in certain locations. Satellite-based broadband services have a latency on the order of several hundred milliseconds (compared with under 20 msec for most wired land-based systems), which is fine for corporate data transmission but annoying to users for Web browsing.

Marketplace

In the fixed wireless broadband marketplace, many carriers and service providers are starting to provision broadband wireless for business and enterprise customers. Sprint Broadband Direct provisions 2 Mbps MMDS services, typically in a matter of days. MCI WorldCom is also making significant inroads into the MMDS market. Players in the higher-frequency LMDS market include Teligent, NextLink Communications, WinStar Communications, and others. AT&T is, of course, also a major player in the fixed wireless broadband market.

In the mobile wireless broadband market, the emerging players are currently Ericsson and Nokia, with their pre-third generation (3G) broadband cellular initiatives known as 2.5G.

In the satellite-based broadband wireless market, major players include DirecPC and StarBand Communications, both of which offer nationwide coverage. Tachyon also provides 2 Mbps service across the United States.

Notes

The Institute of Electrical and Electronics Engineers (IEEE) is standardizing fixed broadband wireless technologies under the new 802.16 group of standards.

B

broadcast domain

The collection of all stations on a network that can receive broadcast messages from any station among them.

Overview

Broadcast domains and collision domains are two different things:

- **Broadcast domains:** These are defined by broadcasting only as all those stations that can receive a broadcast.
- **Collision domains:** These are defined by any type of transmission, including unicasting, multicasting, and broadcasting.

Examples of broadcast domains include

- All stations connected to a given group of hubs or switches
- All stations on an internetwork whose routers are configured to forward broadcasts (not a desirable configuration)
- All stations in a given virtual local area network (VLAN) configured on a group of Ethernet switches.

Notes

Bridges used to segment Ethernet networks divide collision domains but do not divide broadcast domains.

See Also: collision domain

broadcast frame

In Ethernet networks, a frame broadcast to every station on the network.

Overview

An Ethernet media access control (MAC)–layer broadcast frame has a hexadecimal MAC address of FF-FF-FF-FF-FF-FF. This hexadecimal address is equivalent to 48 binary “ones.” The meaning of this address in Ethernet is simply that this frame is intended to be received and processed by every connected node on the network.

Broadcast frames are typically generated when network services make announcements of their presence and availability to other hosts on the network. Too many broadcast frames on a network can degrade communication between nodes on the network.

Notes

In routed internetworks, routers are usually configured not to forward broadcast frames to other subnets. The reason is to prevent broadcast storms in one subnet from overwhelming hosts in other connected subnets. As a result of this limitation, however, broadcast frames used as service announcements are usually limited in scope to the local subnet on which the host providing the services is located.

See Also: broadcasting, broadcast packet, broadcast storm, directed frame, frame

broadcasting

A network communications method in which a packet or frame is sent simultaneously to all stations on the network.

Overview

Broadcasts take place when broadcast frames (or packets) are sent out over the network. These frames contain a special address that instructs every station on the network to accept and process the frame’s contents.

Broadcasts have various functions on a network, including

- Announcing the availability of network services
- Resolving host names into addresses
- Troubleshooting and testing network connectivity

Examples of Internet Protocol (IP) services that employ broadcasts include

- Address Resolution Protocol (ARP)
- Dynamic Host Configuration Protocol (DHCP)
- Domain Name System (DNS)
- NETBIOS

Broadcasts are usually not an efficient use of network bandwidth, since only one or a few network stations might actually be interested in the information being broadcast. For this reason, directed frames (or packets) are used for most network communication, which involves targeting a packet directly for the intended station. (All other stations ignore the directed packet.) Another alternative is multicasting, which involves a form of limited broadcast to a select group of hosts.

Notes

Certain network conditions, such as certain types of device failure, can generate large numbers of unwanted broadcasts. These broadcast storms can sometimes bring down a network if the condition is not resolved.

Applications that are poorly designed may sometimes employ unnecessary amounts of broadcasting, with resulting degradation of overall network services.

See Also: *broadcast frame, broadcast packet, multicasting, unicasting*

broadcast packet

In Internet Protocol (IP) networks, an IP packet broadcast to every host on the network.

Overview

Broadcasts can be used in any type of IP network, including class A, B, C, D, and E networks. The actual broadcast address depends on the class of network under consideration. For example:

- For a class A network 27.0.0.0 the address for a broadcast packet would be 27.255.255.255.
- For a class B network 139.65.0.0 the broadcast address is 139.65.255.255.
- For a class C network 207.17.125.0 the broadcast address is 207.17.125.255.

The general broadcast address 255.255.255.255 is called a local area network (LAN) broadcast and can be routed to every host on an internetwork if routers are allowed to forward broadcasts. A faulty device that pro-

duces excessive 255.255.255.255 packets is said to be “flooding” the internetwork with broadcasts, and this can lead to a condition called a “broadcast storm.”

The common denominator in these examples is 255, which is the decimal representation of the binary octet 11111111. Thus, the LAN broadcast address 255.255.255.255 in binary notation is a series of 32 binary “ones.”

See Also: *broadcasting, broadcast frame, broadcast storm, directed packet, packet*

broadcast storm

A network condition in which so many broadcasts are occurring that normal communication between hosts is disrupted.

Overview

Broadcast storms commonly occur on Ethernet networks where baseband transmission technologies allow only one station to transmit at a time. The presence of broadcast storms often indicates that a networking component is malfunctioning and is continually sending out broadcast messages. A typical situation might be a failed transceiver on a network interface card (NIC) that is continually sending out a stream of binary “ones.”

During a broadcast storm, the wire is continually busy and no other station is able to transmit information over the network. As a result, a broadcast storm essentially brings down the network. Since routers often are not configured to forward broadcast frames between subnets, broadcast storms usually are confined to a single subnet (configuring routers to forward broadcasts is thus a bad idea as a broadcast storm in one subnet could bring down the entire internetwork).

Broadcast storms might also indicate that your network’s bandwidth is nearly saturated and needs to be upgraded.

B

brouter

Any network device having the capabilities of both a bridge and a router.

Overview

Usually, a brouter acts as a router for one protocol (for example, Transmission Control Protocol/Internet Protocol [TCP/IP]) and a bridge for all other protocols (for example, Internetwork Packet Exchange/Sequenced Packet Exchange [IPX/SPX]). Network services often send their announcements over every protocol on the network, which generates additional traffic and makes it generally disadvantageous to run more than one protocol on a single network.

Brouters are not common anymore, however, and the solution adopted by most network designers nowadays is to use a single protocol for all network communication on the main portion of the network, with gateways connecting to segments running other protocols. The protocol of choice for most internetworking today is TCP/IP.

browse list

The list of available shared network resources on a Microsoft Windows network.

Overview

The browse list is maintained and distributed by the Computer Browser service. The browse list contains a list of all available domains, workgroups, and servers on the network. This list is then distributed to clients who desire to connect to shared resources on the network so that they can locate and connect to these resources.

Essentially, when you are browsing Network Neighborhood in Windows NT or My Network Places in Windows 2000, Windows XP, or Windows .NET Server, you are looking at a representation of the browse list for your locally accessible network.

Notes

The browse list is maintained by the master browser computer, but clients that need it obtain it from backup browsers on the network.

If a server or domain is not heard from by the master browser after three announcement periods (amounting to approximately 45 minutes), the server or domain is removed from the browse list.

See Also: Computer Browser service, election

browser (Computer Browser service)

Any Microsoft Windows machine that is running the Computer Browser service and participates in updating and maintaining the browse list of shared resources available on the network.

See: Computer Browser service

browser (Web browser)

A client application that supports Hypertext Transfer Protocol (HTTP), the language of the World Wide Web.

See: Hypertext Transfer Protocol (HTTP), Web browser

browsing

Generally, the process of exploring the shared resources available on a network or the Web content available on the Internet.

Overview

You can browse for shared resources on a Microsoft Windows network using Windows Explorer, My Network Places, and other tools. Browsing a Windows network is made possible by the Computer Browser service, which keeps track of all shared resources on a Windows NT network and communicates this information to clients when they need to access a resource. The Computer Browser service is at the core of the ability to locate shared file and printer resources on a network and maintains the browse list, the list of available shared resources.

Regarding the Internet, the term *browsing* refers to the process of using a Web browser such as Microsoft Internet Explorer, Netscape Navigator, or Opera Software's Opera to view and download Web pages from the Internet. The origin of the term probably stems from the idea of reading magazines, in which you pick up one

magazine and skim through its contents, then go to another magazine, and so on. On the Internet, it is even easier. You do not have to “pick up” anything; you simply keep clicking the links.

BSD

Stands for Berkeley Software Distribution, a family of UNIX operating systems.

Overview

BSD UNIX was developed in the 1970s at the University of California at Berkeley, which licensed the UNIX operating system from AT&T and then made a number of modifications and enhancements, including many common UNIX features such as the vi editor, the C shell, and Transmission Control Protocol/Internet Protocol (TCP/IP) networking.

BSD UNIX and its offshoots constitute one of the two most popular families of UNIX in use today, the other family being UNIX System V and its offshoots. BSD UNIX formed the basis of the SunOS from Sun Microsystems, but Sun later combined features of both BSD and System V into their popular Solaris operating system. BSD UNIX is older than Linux but has not attracted as much attention as Linux has lately.

The major flavors of BSD UNIX popular today include

- **FreeBSD:** A free version of BSD UNIX available for the Intel x86, DEC Alpha, and PC-98 architectures. FreeBSD is the most popular of the BSDs and has a large and active developer community. FreeBSD has been popular with many Internet service providers (ISPs) as the base platform for their Web and mail servers. The current release of FreeBSD is version 4.3.
- **OpenBSD:** A popular version that stresses security with integrated cryptography and support for SSH1 and SSH2. The current release of this operating system is OpenBSD 2.9, and it is also available for free.
- **NetBSD:** Another free version of BSD UNIX that has been incorporated as the base operating system of a number of commercial products. The current release is NetBSD 1.5.1.

Notes

The commercial version BSDi is now known as iXsystems and is licensed by Wind River Systems.

BSP

Stands for business service provider, an application service provider (ASP) that offers a wide range of online business services that include not just Web hosting and e-commerce services typical of ASPs but also customer relations management, desktop maintenance support, system integration and consulting services, and other value-added business services.

building-block services

A component of Microsoft Corporation's .NET platform that provides core Extensible Markup Language (XML) Web services.

Overview

Building-block services provide consistency and ease of use across services and applications developed for the .NET platform. These services are used to move the control of data from applications to the users who use these applications and ensure that user content forms the basis of all transactions.

Microsoft is developing a number of different building-block services to empower developers for rapid development of .NET Web services. Examples of these include services for

- User identification (for example, Microsoft Passport)
- User preference management
- Message delivery
- Calendar management
- File storage

B

While Microsoft is developing the core set of .NET services, third-party partners will develop additional services to build in enhanced functionality to .NET applications and services.

Building-centric Local Exchange Carrier (BLEC)

A telecommunications carrier focused on the Multi-tenant Unit (MTU) market.

Overview

With the increasing deregulation of the U.S. telecommunications industry over the last decades, several different types of local exchange carriers (LECs) have emerged in the marketplace, including Incumbent Local Exchange Carriers (ILECs) and Competitive Local Exchange Carriers (CLECs). The latest of these is the Building-centric Local Exchange Carrier (BLEC), which represents a carrier focused on providing broadband telco services within multitenant units (MTUs). An MTU is essentially a building or group of buildings that primarily host small and medium-sized businesses with between 10 and 200 employees. Examples of business environments serviced by BLECs include office skyscrapers, industrial parks, and hotels. Some BLECs also target residential apartment blocks and malls as well. By targeting MTUs, BLECs are essentially focusing on a market that ILECs have generally neglected (ILECs have historically focused on the large-enterprise and individual consumer markets instead). The requirements of BLEC clients are usually diverse, and typically include Internet Protocol (IP) data, Web hosting, e-mail, and Internet access, which BLECs offer as value-added data services to traditional voice telephone connectivity.

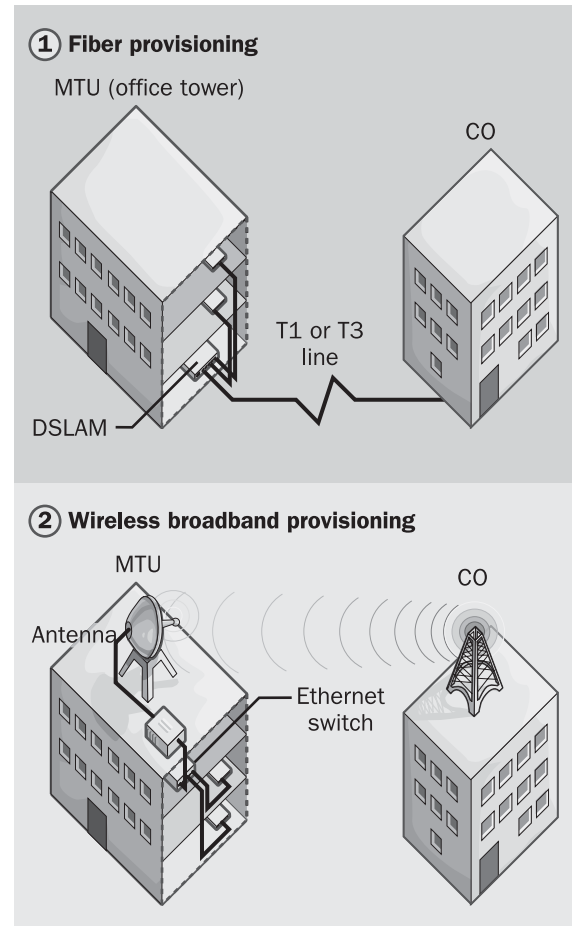

BLECs can typically be grouped into two categories:

- Those focused on retail services to end-user business clients.
- Those focused on the wholesale end of purchasing broadband access for MTUs from inter-exchange carriers (IXCs) who provision these wholesale services. Note that some IXCs themselves are getting

into the MTU market by deploying high-speed metropolitan area networks (MANs) to service such customers and are in effect competitors to BLECs.

Implementation

Typically a single business client within an MTU cannot justify the cost of having a leased line such as T1 deployed to service its needs. That is where BLECs come in, however—they provision such services for all clients within a given MTU.

Building-centric Local Exchange Carrier (BLEC). How a BLEC provisions customers with broadband services.

Typically, a BLEC first has to provide new fiber to an MTU to provide clients with high-speed services

brokered from larger LECs and IXC. This first step is necessary because the majority of large office buildings in the United States do not currently have fiber-optic cabling deployed to them. Once fiber has been laid by the BLEC from the building to the central office (CO) of the LEC or IXC from which the BLEC obtains wholesale broadband provisioning, the BLEC then purchases T1 or T3 services from the LEC or IXC to run over the fiber. Switching gear (usually a DSLAM, an Asynchronous Transfer Mode [ATM] access switch, or some form of high-speed Ethernet switch) is then deployed by the BLEC in the basement of the MTU to provide broadband services to clients throughout the building. This arrangement is preferable to co-locating such equipment at LECs and IXCs and often give BLECs a competitive edge in the speed at which new services can be deployed and problems troubleshot.

Another technology option for BLECs is fixed broadband wireless, which bypasses the initial step of laying fiber to the building. This is often a method for cost-effective provisioning of broadband services for MTUs that is easy to implement rapidly and is often the only solution when the MTU is too far from a central office (CO) for DSL or T-carrier services to be effective.

To provision either of these scenarios, BLECs first have to negotiate right-of-way through revenue-sharing agreements with building owners to gain access to basement wiring closets or deploy rooftop antennas, and this is usually factored into the price for services offered by BLECs to tenants.

Marketplace

Some of the major players among BLECs include Broadband Office, which has right-of-way to a large portion of U.S. commercial office space; Comactive, which is an offshoot of Intermedia Communications; and many others.

Prospects

With increasing deregulation of the telecommunications industries, BLECs find themselves squeezed by rising customer expectations on the one hand, high levees from building owners for fiber and rooftop right-of-way on another hand, and direct competition from CLECs, ILECs, and IXCs higher up on the carrier

feeding chain. Customers owning multiple MTUs desire simultaneous rollout regardless of the up-front costs to BLECs for servicing smaller premises. Some building owners (usually real estate companies) are also consider deploying their own broadband switching gear instead of partnering with BLECs to do so and thus bypass BLECs entirely by going to LECs and IXCs directly. Future rulings of the Federal Communications Commission (FCC) might also affect how this all works out in the marketplace.

Notes

Another common name for BLECs is Multitenant Broadband Service Providers (MBSPs).

built-in account

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a type of user account that is created during installation.

Overview

All computers running Windows 2000, Windows XP, and Windows .NET Server, have two built-in user accounts:

- **Administrator account:** Used to provide administrative access to all features of the operating system
- **Guest account:** Intended to provide occasional users with access to network resources

Depending on whether the computer is a domain controller, a member server, or a workstation, built-in accounts will be either local user accounts or global user accounts. A built-in account on a domain controller is a global user account that exists everywhere within the domain. Users can log on to any machine in the domain using such an account, which provides administrators with the capability of administering a Windows 2000-based network from anywhere on the network. On a member server or workstation, the Administrator and Guest accounts are local user accounts and exist only on those machines.

B

Notes

Rename the Administrator built-in user account to make it more secure.

built-in domain local group

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a domain local group created during installation that has preassigned rights and permissions. Built-in local groups are used to simplify the administrative task of assigning users and groups rights to perform system tasks and permissions to access network resources. Some of these groups include

- **Users:** Contains the Domain Users global group and is used to assign rights and permissions to all ordinary users.
- **Administrators:** Contains the Domain Admins global group and the Administrator account created during setup.
- **Guests:** Contains the Domain Guests global group.
- **Power Users:** Members have the right to share folders and printers.
- **Backup Operators:** Members have the right to back up and restore servers.
- **Account Operators:** Members have the right to administer accounts.
- **Server Operators:** Members have the right to administer servers.
- **Print Operators:** Members have the right to administer printers.

built-in global group

A type of global group created during installation of Active Directory directory service.

Overview

Built-in global groups are created in order to organize common groups of users for administrative purposes. These built-in global groups are created within either

Active Directory (when implemented) or in the Security Accounts Manager (SAM) database (for stand-alone servers). The four types of built-in global groups are

- **Domain Admins:** Initially, this group contains only the Administrator account that was created during setup. Only people with administrative responsibilities should be assigned to this group.
- **Domain Guests:** This group contains the Guest account and is designed for organizing temporary users of network resources and granting them access.
- **Domain Users:** When a new user account is created, it is automatically added to this group, whose function is to collect all ordinary users for the purpose of assigning them permissions to resources on the network.
- **Enterprise Admins:** This group contains users who are assigned administrative rights over the entire network. The Enterprise Admins global group should be added to the Administrators domain local group in each of your network's domains. By default, the Administrator account is a member of the Enterprise Admins group.

built-in group

In Microsoft Windows 2000 and Windows .NET Server, a type of group created during installation to simplify the delegation and assignment of common administrative tasks.

Overview

Built-in groups have preassigned sets of user rights, and some also have preassigned members.

Windows 2000 and Windows .NET Server contain three kinds of built-in groups:

- **Built-in domain local groups:** These are used to assign predefined sets of rights and permissions to users and groups of users, and they exist on all computers running Windows 2000 and Windows .NET Server.

- **Built-in global groups:** These groups are used to automatically organize users into common groups for administrative purposes, and they exist only on Windows 2000 and Windows .NET Server domain controllers.
- **Built-in identities:** These are used by the operating system to automatically group users for system purposes, and they exist on all computers running Windows 2000 and Windows .NET Server.

Notes

You cannot rename or delete a built-in group, and you cannot change the membership of a built-in identity.

See Also: *built-in global group, built-in domain local group*

built-in identities

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a term used to refer to what were known in Windows NT as system groups.

Overview

Built-in identities can represent different subsets of users in different situations, and they do not have a specific membership that administrators can modify. However, you can assign built-in identities rights and permissions for accessing resources or performing system tasks. Examples of built-in identities include

- **Everyone:** Represents all users who can be, or are, on the network, whether from trusted or distrusted domains.
- **Network:** Represents all users who can access, or are accessing, network resources over the network. It does not include users logged on locally to a machine and accessing those resources locally.
- **Interactive:** Represents all users who can be, or are, currently logged on locally to a computer to access local resources on it. It does not include users who can access, or are accessing, network resources over the network.

burst

A condition in which network activity rises suddenly for a short period of time.

Overview

A burst is a transient elevation in network activity, and a network on which a lot of bursts occur is said to be bursty. Bursty networks have different bandwidth requirements than networks on which the traffic is steady, and they need to be designed accordingly. For example, a network on which large video files are frequently transmitted tends to be bursty in its traffic flow.

Bursts can be indicative of a sudden increase in demand for network resources, or they can indicate hardware or software problems. Some networking components are capable of briefly sending data at speeds greater than normal transmission speeds; this is referred to as “operating in burst mode.”

A good first step in accommodating bursty conditions is to use Ethernet switches instead of hubs for concentrating your network connections.

bus

A linear circuit path that can be used to connect multiple devices for exchange of data.

Overview

The idea of a bus in computer networking technology is analogous to that of a bus as a means of transportation: a bus travels over a fixed route across a city, carrying people and stopping at various points for people to get on or off. In the same way, computers and networks use buses to transport data from one device to another. The point on a bus where a device can be connected is generally called a slot.

Buses generally fall in three categories: system buses, peripheral buses, and network buses (or bus topology networks).

System buses are internal to computer systems and are used to carry data between the processor, chipset, memory, disk subsystem, video subsystem, and peripheral

B

cards such as network adapters and sound cards. Examples of different types of system buses include

- **Processor bus:** This transports data between the CPU (central processing unit) and the chipset.
- **Memory bus:** This transport data between the memory subsystem, CPU, and chipset.
- **I/O bus:** This transports data between the CPU, chipset, memory subsystem, and internally attached peripherals such as network adapters, video adapters, and disk controllers.
- **Cache bus:** This transports data between the CPU and the L2 cache (present only in sixth-generation processors such as the Pentium III).

When the term *bus* is used in conjunction with computer systems, it is commonly interpreted as meaning input/output (I/O) bus. The I/O bus has gone through many changes over the years, including the following:

- **Industry Standard Architecture (ISA) bus:** The 8-bit ISA bus was developed by IBM in 1981 for the original IBM PC. A 16-bit version was then developed in 1984 for the newer IBM AT. Some desktop systems still include an ISA bus and slots for backward compatibility of legacy peripheral devices, but the presence of an ISA bus is problematic because it does not support plug and play (PnP).
- **VESA Local Bus (VLB):** This was used by some 486 systems but had the disadvantage that the bus was essentially an extension of the CPU's leads, which resulted in poor performance.
- **Peripheral Component Interconnect (PCI) bus:** This is the most common form of I/O bus in use today, and it comes in both 32-bit (PCI 2.0) and 64-bit (PCI 2.1) versions.

Peripheral buses are buses whose primary use is for connecting peripherals to computer systems or network switches. Examples of this type include Small Computer System Interface (SCSI) and Fibre Channel.

Network buses (or bus topology networks) represent any form of network in which devices are connected

together in linear fashion. Examples include 10Base2 and 10Base5 Ethernet and Token Bus networks, all three of which are obsolete. Most networks today are based on a star topology, which is easier to manage than bus topology because of its centralized nature.

Prospects

The state of system bus technology is currently in flux. Whereas previously networks could not keep up with their servers, now the server has become the bottleneck: a Peripheral Component Interface (PCI) local bus has a difficult time performing I/O fast enough to fully utilize a Gigabit Ethernet (GbE) network connection. The result has been various industry initiatives to speed up the I/O bus to match rapidly growing network capacity (10 GbE is now on the horizon). Another source of pressure has been the increasing need for modern servers to be able to rapidly access large amounts of database storage, sometimes in the terabyte range.

Some of the newer industry initiatives for evolving system buses include

- **PCI-X (or PCIx) bus:** This proposed next-generation PCI bus will have a theoretical data transfer rate of 1 gigabit per second (Gbps), based on a clock speed of 133 megahertz (MHz), and is backward-compatible with existing PCI peripherals. A draft standard for PCIx was produced in 1999.
- **Infiniband:** Unlike legacy bus systems (including PCI), which are shared-bus systems in which connected devices must contend with each other for the right to transmit data, Infiniband is a switched-bus fabric that is capable of data transfer rates of 6 Gbps or higher and is supported by industry heavyweights such as IBM and Intel Corporation.
- **Ethernet:** Since high-speed switched Ethernet performs so well in the network, why not use it for I/O within computer systems? This is the thinking of Performance Technologies, which has joined with other manufacturers in proposing a new form of PCI bus called cPCI based on switched Ethernet technologies that provides 2 Gbps of dedicated bandwidth per slot.

Other proposals include using high-speed SCSI technologies (such as Ultra160 SCSI) and FiberChannel for internal system buses, but these initiatives have not gained much momentum.

Notes

A bus and a port are both similar in that they transport data between devices, but although a port can be used only to connect two devices, a bus can connect three or more devices.

business logic

That portion of an application that reflects the actual way the enterprise does business.

Overview

Business logic is a term used in writing applications for Microsoft Transaction Server (MTS) using reusable COM+ components. These components represent a combination of logon verifications, policies, database lookups, validation edits, and other processes that constitute how business is done in the enterprise. An application's business logic specifies how the component's programming logic reflects the actual way the enterprise does business. Business logic enables consistent and logical processing of business data.

A representation of a real-world component of the enterprise's business is called a "business object." Examples of business objects include customers, orders, products, invoices, and anything else that can be encapsulated in an application's business logic and manipulated by its users.

bus topology

A networking topology that connects networking components along a single cable or that uses a series of cable segments that are connected linearly.

Overview

A network that uses a bus topology is referred to as a "bus network." Bus networks were the original form of Ethernet networks, using the 10Base5 cabling standard. Bus topology is used for

- Small workgroup local area networks (LANs) whose computers are connected using a thinnet cable
- Trunk cables connecting hubs or switches of departmental LANs to form a larger LAN
- Backboning, by joining switches and routers to form campus-wide networks

Bus topology. A simple example of a bus topology network.

B

Bus topology is the cheapest way of connecting computers to form a workgroup or departmental LAN, but it has the disadvantage that a single loose connection or cable break can bring down the entire LAN.

Notes

A hub or concentrator on an Ethernet network is really a collapsed bus topology. Physically, the network appears to be wired in a star topology, but internally the hub contains a collapsed bus, creating a configuration called a star-wired bus. However, in this case, a failure in one of the cables does not affect the remaining network.

Communication problems on bus networks might indicate that the bus ends are improperly terminated. A break in the cable will produce a similar result, since the ends of the break are not terminated. Use a cable tester to determine the problem's nature and location.

C++

The most widely used object-oriented programming language.

Overview

C++ is the standard programming language used for developing tools and applications for high-speed networking. This is because it is a compiled language whose object code is essentially native assembly language and hence runs extremely fast. For example, a form handler written for a Hypertext Markup Language (HTML) form that runs on a UNIX Apache Web server will run much faster if it is written in a compiled language such as C or C++ than if it is written in an interpretive language such as Perl or Microsoft Visual Basic, Scripting Edition (VBScript).

High-performance Internet Server API (ISAPI) applications and dynamic-link libraries (DLLs) written for Microsoft Internet Information Services (IIS) generally perform best when written in C++. Powerful distributed Web-based applications for the Internet can be developed using a combination of Active Server Pages (ASP) scripts in VBScript or JScript, with Microsoft ActiveX components and ISAPI dynamic-link libraries (DLLs) written in C++ using Microsoft Visual C++.

C++ programs for Windows network operating system platforms can be developed using a variety of tools:

- Traditional C++ development tools using editors, compilers, and debuggers support low-level application programming interface (API) access, Microsoft Foundation Classes (MFC), software development kits (SDKs), and other supporting elements.
- Rapid application development (RAD) tools provide integrated development environments (IDEs) that focus on providing developers with ease-of-use features.
- Component deployment tools take a component-based approach to generating and reusing C++ code for building distributed and multitier applications.

C++ is based on the earlier C language that is used for developing applications, including Win32 applications for Microsoft Windows platforms. The standard form of C++ is called ANSI C++ and is defined by the American National Standards Institute (ANSI).

Notes

Microsoft Visual C++ combines the best features of these various classes of tools. It is an excellent choice for developing large-scale distributed networking applications based on the C++ language and Microsoft Corporation's own specific extensions to ANSI C++ that are designed for the Win32 platform.

C#

Pronounced "C sharp," a programming language developed by Microsoft Corporation for its new .NET platform.

Overview

C# is an offshoot of C and C++ that is designed for rapid development of Web services for Microsoft's new .NET platform. C# is derived from C++ and has much of the power of C++ while improving on it in many respects from the point of view of the developer who needs to rapidly create and deploy applications in the e-economy.

The main weaknesses of C++ as a development environment are its complicated code-compile-debug development cycle, its potential of creating memory leaks that are difficult to troubleshoot, and the requirement of having applications explicitly manage memory resources. C# is similar to the Java platform developed

C

by Sun Microsystems in that memory resources and garbage collection (object lifetime management) are automatically handled by the language itself, freeing developers to work on creating applications instead of being bothered by handling these intricate details. C# also simplifies access to external objects and simplifies the object creation process compared with C++. And although C++ applications require frequent use of include files to allow access to system services, in C# these services are transparently wrapped in objects. Like Java, C# thus relieves programmers of much of the chore of object and memory management, speeding up the development cycle in the process.

On the other hand, C# is unlike Java in that it maintains powerful features such as pointers, passing arguments through reference, overloading operators, and manually allocating memory. These features, basic to C++, are included in C# to provide programmers with the functionality should they need it, but they are deemphasized in C# compared to their common use in C++. For example, when pointers are used in C#, they need to be tagged in a section of code marked as “unsafe,” making it easier to troubleshoot difficulties that may arise from their misapplication. Furthermore, C# has the advantage over Java of providing direct access to native Microsoft Windows services, and C# is easier to learn than Java for C++ programmers because its syntax is derived from and is similar to C++, whereas the syntax for Java has many differences from C++ that make it difficult for C++ programmers to use easily.

It is relatively simple to port existing C++ programs to C# (by contrast, it is much more difficult to port such applications to Java). The main disadvantage of C# as a development environment is a weakness shared with Java: unlike C++, which compiles programs into native machine code, C# compiles programs into an intermediate bytecode called intermediate language (IL) that is then interpreted by the .NET runtime. This means C# shares a performance hit similar to Java, which is also an interpreted platform. C++ will still be used for writing code modules where the best performance possible is required (such as device drivers), but C# performs sufficiently well on today’s hardware platforms to be

used as a primary development platform. And because C# executes on the .NET runtime, it shares the interoperability features of this runtime, which allows modules written in C# to communicate with code written using other programming languages.

Microsoft plans to submit the C# language to the standards board of the European Computer Manufacturers Association (ECMA). The ECMA will then manage the language as a standard, which means that third parties wanting to use C# to develop applications will not be required to pay licensing fees to Microsoft. This will keep the cost of development tools and applications development low.

Notes

The Object Management Group (OMG), the creators of Common Object Request Broker Architecture (CORBA), is developing a language mapping for C# to enable it to communicate through CORBA with applications written in other languages such as C, C++, Cobol, Java, Python, and Ada.

C2

A security standard for computer systems established by the National Computer Security Center (NCSC).

Overview

The NCSC is a U.S. government agency responsible for evaluating the security of software products. The C2 security standard is defined in the Trusted Computer Systems Evaluation Criteria (TCSEC) manual (or Orange Book) published by the NCSC.

The NCSC rated Microsoft’s Windows NT 3.5 (with Service Pack 3) C2-compliant. The C2 designation assures that the base operating system satisfies a number of important security criteria. This designation also represents an independent, unbiased evaluation of the system architecture’s security with regard to the government’s operating and implementation standards. Windows 2000 also supports C2, but is still undergoing the NCSC evaluation process.

A C2 rating does not indicate that a system is free of security bugs; instead, this rating certifies that the computer system's underlying architecture is suitable for high-security environments in specific networking configurations. It is incorrect to say that Windows NT is C2-certified or runs in C2 mode. Only a complete computer system (including hardware) can be rated C2. A rating of C2 means that in a particular implementation, in a particular networking environment and configuration, using specific hardware and software, a computer network using a Windows NT operating system can apply for, and might receive, C2 certification.

According to the Orange Book, in a C-level system, the security policy must be based on what is known as Discretionary Access Control (DAC), which essentially means that users of the system can own objects (such as files and directories) and can control access to these objects by other users. A user who establishes control over an object is responsible for granting or denying all access rights to that object. In other words, the owner of an object grants or denies users access to the object at his or her discretion. This is in contrast to a B-level system, in which Mandatory Access Control (MAC) specifies that all objects have security levels that are defined independent of the object's owner.

cabinet

An enclosure with a built-in rack for holding and organizing patch panels, switches, hubs, routers, servers, and any other networking equipment within a wiring closet.

Overview

Cabinets can be wall-mounted or freestanding, come in various heights, and are usually standardized for 19-inch-wide shelving and paneling. They generally come in 83-inch and 48-inch heights, although many vendors offer custom-designed cabinets. The reason for standardizing the width to 19 inches (18.31 inches to be precise) is that hubs, switches, routers, and other networking devices are produced in this width so that they can be organized in racks and cabinets designed for this purpose. Cabinets come with a variety of accessories for organizing cables, power strips, and other equipment. Because heat can accumulate in cabinets, they usually include vented walls and have an exhaust fan on top. A cabinet will often have a locking front panel made of clear plastic so that status lights on equipment are easily visible. Shelves can be fixed, mounted, or sliding to enable easy access to the sides and backs of equipment.

Cabinet. A typical cabinet for mounting networking and telecommunications equipment.

Notes

When should you choose a cabinet instead of a rack? Choose a cabinet for equipment that is exposed to user traffic, and then you can lock equipment away when the room itself is not locked. Cabinets are also best for expensive networking equipment that you do not want anyone but authorized administrators to touch. Cabinets

C

with filter fans installed can protect equipment in environments where dust is a problem. Use filler panels to enclose areas of the cabinet that are not occupied by equipment.

cabinet file

A file with the extension .cab that stores compressed files, usually for distributing software on Microsoft platforms.

Overview

Cabinet files can contain multiple files in a compressed state, or a single compressed file can be spread over several cabinet files. During installation of software, the setup program decompresses the cabinet files and copies the resulting files to the user's system.

Cabinet files can be digitally signed using a Microsoft technology called Authenticode. This allows setup files to be downloaded safely over distrusted networks such as the Internet. Cabinet files are compressed using a compression algorithm called MSZIP, which is based on the Lempel-Ziv algorithm.

Notes

Cabinet files in Microsoft Windows 95 were located in the Win95 directory on the source CD, and most were represented as a series of large files with names such as Win95_1.cab and Win95_2.cab. Windows 98 uses a different naming convention and names many of its smaller cabinet files by function rather than by the order in which they are used during setup. Naming by function makes the extraction of files easier, which in turn makes the setup process smoother.

In Windows 95, if you want to extract specific operating system files from a cabinet file (for example, to replace a missing or corrupt file), you have to use the command-line utility called extract. Using Windows 98 and later versions, you can simply double-click on a cabinet file using Windows Explorer to view its contents in a new window, double-click on the specific file you want to extract, and specify the destination folder to send it to.

You can also use the System File Checker tool to extract files without knowing which specific cabinet file they are located in.

cable modem

A device that allows your computer to access the Internet through dedicated broadband transmission networking services by means of your home cable TV (CATV) connection.

Overview

Cable modems modulate and demodulate analog signals like regular modems, but for transmission over broadband video services instead of telephone voice services. A cable modem can be internal or external and can interface with the coaxial cable connection at the user's end and the Cable Modem Termination System (CMTS) at the cable provider's head office.

Cable modem and Asymmetric Digital Subscriber Line (ADSL) are competing technologies for bringing high-speed broadband Internet services to homes and businesses. Cable modems offer downstream speeds of 10 megabits per second (Mbps) and higher, but competing technologies, lack of standards, and implementation costs have slowed widespread deployment and use of this technology.

There are two basic types of cable modem services:

- **One-way cable modems:** These are used by unidirectional cable service providers. Most cable TV services are designed to carry information in one direction only—from the broadcaster to the customer premises. With one-way cable modems, the customer uses a regular telephone modem to send information to the cable company but uses the cable TV system with cable mode to receive signals from the company. The telephone modem handles all upstream communication, and the cable modem handles all downstream communication. One-way cable modems are typically cards installed inside a subscriber's computer.

- **Two-way cable modems:** These require that the broadcasting cable company has converted its cabling and repeater infrastructure for bidirectional communication. Two-way cable modems are typically external devices connected to a network interface card (NIC) that is installed in the subscriber's computer. The cable modem is used for both upstream and downstream communication in this configuration. Most cable companies currently have initiatives under way to make such a conversion, but it requires a large capital investment. Therefore, it will be several years before these systems become widely available.

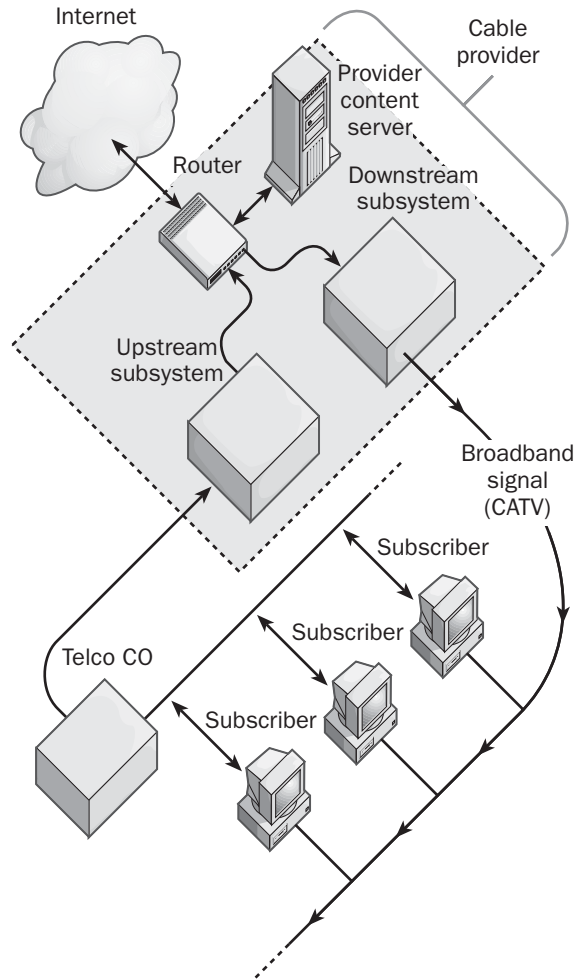

Implementation

In a typical one-way cable modem implementation, the CMTS uses separate subsystems for upstream and downstream connections that terminate at a router. The downstream subsystem is designed for converting incoming Internet Protocol (IP) traffic into radio frequency broadband signals that are broadcast using a broadband network hub (BNH) over cable TV wiring to local groups of connected subscribers. The upstream subsystem usually consists of banks of ordinary telephone modems to allow for easy expansion of services to additional subscribers. The router is used to route network traffic between clients and local content servers hosted by the cable provider, and to the Internet.

Downstream traffic is typically modulated using 64 or 256 Quadrature Amplitude Modulation (QAM) and can achieve speeds of 27 Mbps or higher. Upstream traffic is encoded using 16 QAM or Quadrature Phase Shift Keying (QPSK) and typically ranges from 320 kilobits per second (Kbps) to several Mbps.

Marketplace

Excite@Home was an early player in the cable modem marketplace, and many local cable companies followed offering high-speed Internet access to their cable TV subscribers. Consolidation in the industry has led to the emergence of several major players, including AT&T Broadband and AOL/Time Warner.

Cable modem. A one-way cable modem service.

Cable modem Internet access costs around \$40 a month in most locations but, because their operation depends on the wiring infrastructure of cable TV systems, cable modems are almost exclusively offered for residential customers and home-based businesses. Some cable modem providers such as Cox Communications also compete with telcos by offering voice as well as data services.

C

The cable modem market is growing more rapidly than the Digital Subscriber Line (DSL) market, its main competitor. This is happening despite the security and bandwidth issues associated with cable modems (see below), and is driven largely by the complexity of DSL compared to the simplicity of cable modems and by the fact that cable modems are not limited by the 3-mile (4.8-kilometer) distance restriction that governs how far a DSL customer can be from the DSL provider's central office (CO). A Federal Communications Commission (FCC) survey found that cable modem subscribers in the United States grew from just over 100,000 in 1998 to almost 1 million in 1999. In 2000 worldwide cable modem usage was estimated at over 6 million subscribers, almost twice that of DSL.

Issues

Most cable television companies have jumped on the cable modem bandwagon to offer Internet access for their customers, but this has not been without problems. Existing tree-and-branch coaxial systems were built for one-way transmission and often require expensive upgrades to make them suitable for two-way data transmission. Some of the steps typically involved in the upgrade are upgrading core distribution networks to fiber (creating a hybrid fiber-coax network) and troubleshooting ingress noise due to poor shielding and loose connectors.

Many cable operators, although they support multi-megabit upstream data speeds, have instead restricted upstream speeds to 128 Kbps or lower to help prevent customers from running rogue Web servers on their network in violation of their customer agreements. Also, all subscribers in a one-way cable modem local service area are essentially on a local area network (LAN) and, if they have a packet sniffer, they can see one another. If you are using a one-way cable modem with Microsoft Windows on your computer, you should disable file and print sharing so that other users in your local service area cannot see your system or access resources on it. The cable modem industry itself has proposed a solution to the security issue through an initiative called Data Over Cable Service Interface Specification (DOCSIS) that specifies encryption of all cable modem traffic

using 56-bit Data Encryption Standard (DES), although DES is no longer secure.

Furthermore, although in theory a cable modem might support downstream transmission speeds of 10 Mbps or higher, in practice downstreams may be significantly less than 1 Mbps. This is because all cable modems serviced by a given neighborhood Cable Modem Termination System (CMTS) are essentially on a LAN and share the available bandwidth. Thus, the more modems deployed in a given neighborhood, the slower the system performs for Internet access, especially when some users are downloading large files or streaming media (a common occurrence among cable modem users). In this respect DSL has an advantage because it is a secure, private connection directly to the Internet.

Notes

If you have a one-way cable modem installed on a computer running Microsoft Windows 2000, Windows XP, or Windows .NET Server and it is not working properly, you might have IP Auto-Configuration Addressing enabled, causing an addressing problem that prevents packets from being routed successfully to your machine. Also, try checking with your cable service provider to determine whether you have correctly configured the line-in frequency, line-out phone number, and proxy server address.

cable run

A length of installed cable connecting two network components that are not in immediate proximity to one another.

Overview

Laying cable runs is the main work of installing premise cabling in a customer premises. Types of cable runs include

- **Horizontal cable:** Runs through building plenums (the space between the floor and the ceiling) and

false ceilings, connecting wiring closets together and connecting patch panels to wall plates

- **Vertical cable:** Runs through vertical building rises, connecting wiring closets on each floor with the building's main equipment room

Different grades of cabling must be used for different runs to ensure compliance with building codes and safety standards. Examples include polyvinyl chloride (PVC) cabling and plenum cabling. The Electronic Industries Association/Telecommunications Industry Association (EIA/TIA) wiring standards specify guidelines for using cable types and grades.

Notes

Cables connecting computers to patch panels (drop cables) and connecting patch panels with hubs and switches (patch cables) are not generally referred to as cable runs because they are not permanently installed and are usually quite short. The term *cable run* generally applies to cables that run from the patch panels in a wiring closet to other parts of the building.

When installing horizontal or vertical cable runs, use the highest grade that your budget will allow in order to accommodate future upgrades of your network's speed and bandwidth. Use the enhanced Category 5 (Cat5e) cabling—which is a variety of unshielded twisted-pair (UTP) cabling—for all copper cabling installations. If you can, install parallel vertical runs of fiber-optic cabling with copper cabling in vertical rises to allow for future expansion of your network backbone. Installing two cables at once saves costs later, even if you need only the copper cabling now.

cable tester

Any device for measuring the integrity and transmission characteristics of cabling.

Overview

Cable testers perform various functions to test network cabling for compliance with cabling standards devel-

oped by bodies such as the Telecommunications Industry Association (TIA), the International Organization for Standardization (ISO), and the International Electrotechnical Commission (IEC). Cable testers are useful to local area network (LAN) administrators, cable installers, and field service providers for testing and certifying cabling installations as compliant with these standards.

Cable tester. A handheld cable tester.

Cable testers come in a variety of forms, ranging from handheld to briefcase size. They are generally divided between those used for testing fiber-optic cabling and those used for testing copper cabling. Different testers have different capabilities, but their general function is to measure various electrical characteristics across different ranges of frequencies. Testers will typically measure some or all of the following parameters at various frequencies from 100 megahertz (MHz) to 350 MHz and beyond:

- Attenuation, which is the decibel decrease in signal strength as a signal propagates through a physical medium
- Impedance, which is the resistance to the flow of alternating current
- Noise, indicated by the floor values for randomly generated electrical signals

C

- Near-end crosstalk (NEXT), which is a decibel measurement of crosstalk taken at the end where a signal is injected
- Attenuation to crosstalk ratio (ACR), which is the decibel difference between NEXT and attenuation values
- PowerSum NEXT, which measures the crosstalk between a single pair of wires and all other pairs in the cable
- The distance to a short or unterminated cable end, used for link-testing the continuity of circuits

Uses

Cable testers are particularly important for testing Category 5 (Cat5) and enhanced Category 5 (Cat5e) structured wiring deployments to see if they will properly support Gigabit Ethernet (GbE) networking. GbE pushes unshielded twisted-pair (UTP) cabling to its limits and requires top-quality properly installed cabling to operate as expected. Particularly in older buildings with existing Cat5 wiring, use a cable tester to measure such parameters as cross-talk and NEXT to determine if packet loss will occur over portions of the network. Particularly vulnerable portions include cable termination at RJ-45 wall jacks and at patch panels inside wiring closets. Poor quality patch cables between workstations and wall jacks are a common problem, as are patch panel connections that have been untwisted beyond the specified limits.

Marketplace

A number of vendors produce different kinds of test equipment for cable testing. Two of the top vendors of such equipment include Fluke Corporation, which offers a wide range of cable testers, and Hewlett-Packard.

Today's cable testers can perform comprehensive and programmable sets of autotests for a variety of cable types. A good cable tester can tell you at the push of a button whether installed wiring can support different kinds of networking architectures—such as coax, 10BaseT, 100BaseT, 100BaseVG, and Token Ring.

Cable testers can also store measurements taken so that they can be analyzed separately afterward.

The most accurate types of cable testers for UTP cabling are those that can test and certify Category 5 (Cat5) cabling to Level II TSB-67 compliance and support the Institute of Electrical and Electronics Engineers (IEEE) TSB95 field testing specifications. An all-in-one cable tester is an invaluable tool and a good investment for the network administrator. It can make up for its cost in higher network availability.

Notes

Use a fiber-optic tester and an optoelectronic light source to test both ends of a new spool of fiber-optic cabling before beginning an installation with this cable. A good fiber-optic cable test should give you not only a pass/fail analysis of an installed cabling setup, but also quantitative values of the optical link capabilities of your wiring configuration.

cabling

Any wires used for connecting computers and networking devices together to enable them to communicate.

Overview

Cabling constitutes the passive portion of any computer network—the active portion consists of the servers, workstations, switches, routers, and other components. Good cabling provides the foundation for creating reliable local area networks (LANs). Cabling is also used for connecting LANs into wide area networks (WANs). Network administrators are usually involved in the deployment of LAN cabling, but WAN cabling is usually the responsibility of the telecommunications carriers whose services are being leased.

Two basic types of cabling are used in LAN networking environments:

- **Copper cabling:** This type consists of insulated copper conductors that transmit signals using electrical voltages and currents. Copper cabling can be

either coaxial cabling (such as thinnet or thicknet) that is used mainly in industrial environments, or the more commonly employed twisted-pair cabling. Twisted-pair cabling comes as either unshielded twisted-pair (UTP) cabling (commonly used in Ethernet or Fast Ethernet environments) or the less common shielded twisted-pair (STP) cabling (employed for token ring networks and sometimes for Gigabit Ethernet [GbE] installations). Copper cabling is mainly used for shorter cable runs such as horizontal cable runs between wiring closets and wall plates in work areas, for patch cables, and for equipment interconnects.

- **Fiber-optic cabling:** This type is made of glass strands that transmit signals as light waves or pulses. Fiber-optic cabling can be either single-mode, which is used for the longest cable runs, or multimode, which has a much higher carrying capacity. Fiber-optic cabling is generally used for backbone cable runs such as vertical rises in buildings and building-to-building interconnects on a campus, for high-speed interconnects between networking devices in a wiring closet, and for connections to high-speed servers and workstations.

Implementation

The process of installing cabling in a building for purposes of computer networking is called establishing premise wiring. Unfortunately, cabling is only as good as the way it is deployed and only as good as the connectors and other elements that help make a computer network. Poor quality cabling, improperly installed cabling, or cheap wall plates and patch panels can make a cabling system perform more poorly than expected, particularly at GbE speeds.

The Telecommunications Industry Association (TIA) and the Electronic Industries Alliance (EIA) have defined a series of standards on the required electrical characteristics of commercial cabling for computer networking and also standards for the proper layout and organization of premise cabling. These standards are called the EIA/TIA wiring standards. The EIA/TIA-568A Commercial Building Telecommunication Cabling Standard specifies standards for each of the following:

- Establishing wiring closets on each floor of the building to contain rack-mounted equipment such as hubs, switches, and patch panels
- Running vertical backbone plenum cabling through building risers and building plenums, for connecting wiring closets to the main equipment room
- Running horizontal polyvinyl chloride (PVC) cabling for each floor through false ceilings
- Connecting the patch panels in the wiring closet to wall plates in computer work areas

Cabling installed in a building must also meet all legal requirements, including federal and local building regulations for fire safety. Do not attempt to wire a building unless you are fully familiar with the regulations.

Choosing the right kind of cabling at the beginning of an installation can save considerable expense when you later upgrade networking equipment for higher transmission speeds. Some tips for successfully outsourcing cabling installations for computer networks in buildings include

- Hiring a qualified cabling consultant to review the scope and details of your plans and procedures. Hire cabling consultants who either have vendor certification (if you are using “channel cabling,” that is, all the cabling components are being purchased from a single vendor) or an independent consultant affiliated with BICSI.
- Ensure that if you outsource your cabling installation that the company you hire is properly licensed and insured for such work.

If you plan to lay cable yourself for your building, here are a few more guidelines:

- Use no more than 30 to 40 pounds of pull when pulling cabling through a conduit or a plenum.
- Do not excessively bend wiring (especially fiber-optic cabling), and be sure not to untwist UTP wires more than specifications allow.

C

- Make sure data wiring and power cables are at least 6 inches (15 centimeters) apart, and, if they need to cross each other, they do this at a 90 degree angle.

Notes

Specialized cables—such as serial, parallel, or Small Computer System Interface (SCSI) cables—are used to connect peripherals and therefore do not serve the same purpose as the cables just discussed. Serial cables and other special purpose cables are generally very short and are not permanently installed.

Note that not all networks use physical cabling. Wireless networks can use infrared, microwave, radio, or some other form of electromagnetic radiation to allow networking components to communicate with each other. A cabled network is sometimes referred to as a wireline network, as opposed to a wireless network.

CA certificate

Also called a root certification, a digital certificate that can be used to verify the identity of the certificate authority (CA) itself.

Overview

The CA certificate contains the identification information and public key for the certificate authority it identifies. A certificate authority that is part of a hierarchical public key infrastructure (PKI) receives its CA certificate from the CA directly above it in the hierarchy. A root CA at the top of a PKI hierarchy must self-sign its own certificate, in effect certifying itself.

The CA certificate plays an important part in the workings of the Secure Sockets Layer (SSL) protocol. The CA's public key, contained in the CA certificate, is used to validate all other digital certificates that have been issued by that CA for entities (individuals, systems, companies, and organizations). When an entity such as a Web browser (perhaps Microsoft Internet Explorer) or a Web

server (perhaps Microsoft Internet Information Services) requests a digital certificate from a CA, the CA certificate identifies the CA that issues the certificate.

This CA certificate is downloaded from a shared storage location at the certificate authority and installed onto the Web server or browser. Later, when the Web browser tries to access the Web server using the SSL protocol, the Web browser uses the CA certificate to validate the Web server's certificate. Similarly, the server can use the CA certificate to validate the browser client's certificate, if it has one.

Notes

The digital CA certificate for a CA must be kept in a location that is readily available for all servers and clients that will access it and install it on their Web browser or Web server. From this location, Web servers and Web clients that need to use the SSL protocol must obtain and install the CA certificate in their certificate stores. On Microsoft Certificate Server, this location is the default Web location http://Server_Name/certsrv, where Server Name is the name of the Microsoft Windows NT server on which Microsoft Certificate Server is installed.

Internet Explorer comes with the CA certificates of a number of certificate authorities preinstalled. These root certificates enable Internet Explorer to be used for functions such as SSL authentication and sending secure e-mail. If you want to use the services of a CA that does not have its CA root certificate installed in Internet Explorer, you can visit that CA's Web site to find instructions on how to obtain its root certificate. Administrators can also use the Internet Explorer Administration Kit (IEAK) for importing and installing root certificates on Web browsers prior to installation on client machines.

caching

Generally, any mechanism for storing frequently needed information in accessible memory so that it can be quickly retrieved. This article focuses on caching as the temporary storage of Web content to enable faster access by users.

Overview

While caching in general has been around a long time and has been implemented in various ways in computer systems and networks (see Notes at the end of this article), caching of Web content has exploded over the last few years into a big industry. In the context of the Internet, caching means the copying of Web content to storage locations near the client so that the client's Web browser can more quickly access the information. Caching speeds up accessing Web content and makes better use of available bandwidth (especially important when the Internet is accessed over slow and costly wide area network [WAN] connections).

While the emergence of broadband Internet access may seem to sidestep the need for caching, this is not really so. Most analysts agree that with the Internet, providing faster access simply drives up demand further and raises expectations, leading to even greater traffic congestion and frustration for users. The solution to bogged-down Internet access is caching.

Implementation

Caching can be implemented in a variety of ways using different systems. The simplest arrangement is deploying cache servers on the network. A cache server is used to speed corporate access to Web content on the Internet by caching the Web pages that users most frequently request. Cache servers reduce network traffic and speed up access to frequently requested content by caching such content. If a user requests a page that has recently been cached, the page will be retrieved from the cache server instead of from the Internet. Pages are held in the cache until they expire.

The cache server locates the content closer to the users who need it than the Web servers that contain the original version of this content. In general, the closer the cache to the user, the faster the response time the user will experience when trying to access this content in a browser. In the enterprise, cache servers are typically deployed at the edge of the corporate network, thus reducing overall WAN link traffic and congestion and saving money. Many firewalls and proxy servers include some form of content caching. Although firewalls and proxy servers are mainly concerned with

securing access between a private corporate network and an distrusted public network such as the Internet, including cache server functionality in these products enhances their overall performance.

Caching. How a simple cache server can improve access time for clients.

Caching servers are also useful in situations where a sudden increase in Web traffic is anticipated, as when a major sports or fashion event will be covered on the Web. In this case, simply throwing bandwidth at the problem of Internet traffic congestions is not a viable solution because increased bandwidth simply leads to increased demand from users. Instead, by preloading content from Web servers to caching servers, users will not overwhelm the Web servers on the day of the event and be disappointed. This use for caching servers is sometimes called “dealing with flash crowd control” or the “instant popularity problem.” By using a network of cache servers in such situations and

C

configuring replication appropriately between them, supply can be scaled for demand at virtually any level.

Dedicated cache servers are also used in high-traffic situations within the Internet backbone itself to reduce congestion on the backbone. Caching servers are often located at Internet service providers (ISPs) and Network Access Points (NAPs) for improving the overall performance and responsiveness of the Internet. This can be used to reduce the effect of bottlenecks on ISP networks and to reduce the cost of local ISPs buying bandwidth from regional ISPs.

Cache servers can even be deployed at the customer premises and configured with preloaded content to speed access to corporate intranets. Such a scenario is similar to the built-in content caching capability of Web browsers, but in this case the content is cached locally on a machine separate from the client machine to improve performance even more.

Types

As far as administrators are concerned, caching servers come in two basic types:

- **Caching appliances:** These are preconfigured servers with preloaded caching software that can easily be dropped into the network by simply connecting them to a backbone switch and turning them on.
- **Caching software:** This includes software from different vendors that can be loaded onto servers and deployed as needed within the network by the administrator. Caching software is especially targeted toward the needs of the corporate enterprise for improving remote access to corporate intranets.

In addition, from the user's perspective, cache servers can be implemented in different ways:

- **Transparent caching:** Here cache servers filter Internet Protocol (IP) traffic to find out which Web pages are most requested in order to determine which pages should be cached and for how long. Transparent cache servers require no special modification or configuration of the client in order to operate, but the cache server itself must be placed at

the edge of the WAN, typically by connecting it to a Layer 4 switch or WAN access router so that every request sent by a client is examined by the cache server first before routing it over the Internet to its intended destination.

- **Proxy caching:** Here the administrator configures the client browsers to send their requests for Web content directly to the cache servers. If these cannot respond to the request (for example, if the page has not been cached or has expired from the cache), the cache server refers the client to the actual Web server hosting the content. This option requires more configuration but gives administrators greater control over what content users can access and provides an extra layer of security.
- **Reverse proxy caching:** Here a group of cache servers typically serves as a front-end to the Web server on the Internet, which hides behind them. User requests go directly to the cache servers, which appear as Web servers to the client. Reverse proxy caching is typically used to deal with flash crowd control discussed earlier.

Cache servers also determine whether to flush content from their cache in different ways:

- **Active caching:** Here the cache server uses intelligent heuristics to determine how long to keep a page in the cache before marking it expired. Many factors can be taken into account, including the requesting IP address, the hit statistics for the page, and how long the page has been cached.
- **Passive caching:** When a client requests a page from the cache, the cache server issues an HTTP GET IF MODIFIED command to the originating Web server to determine if the cache contains the latest version of the page. If not, the cache requests the current version and then forwards this to the client. If the cache does hold the current version, this is returned immediately to the client. The main disadvantage of passive caching is that it introduces the extra step of having the cache server contact the Web server each time a client requests a page, which, unless the cache server is close (in a network sense) to the Web server,

will have the opposite effect from what caching was intended to do—it will slow down the response time instead of speeding it up.

- **Forced caching:** In this case the cache server is preloaded with content that users are expected to frequently access. Forced caching is typically used for improving access to corporate intranets for remote users.

Marketplace

The caching industry has exploded over the last few years, driven by the tremendous growth of the Internet and the demand of users for fast performance in accessing Web sites. In the arena of general caching software, the top players include Microsoft Corporation's Internet Acceleration and Security Server (IAS Server), the successor to Microsoft Proxy Server; Novell's Internet Caching System; and several UNIX-based solutions.

In the arena of prepackaged caching appliances, offerings are available from Dell Computer Corporation's (PowerApp.cache), Compaq (TaskSmart), Cobalt Networks (Qube), Network Appliance (NetCache), and many others. Caching appliances range from those targeted for corporate intranets to powerful caching solutions for ISPs and telecoms.

A number of pure-play caching vendors have had a large impact on the caching market. Some of the big players here include Inktomi Corporation, CacheFlow, and Network Appliance. Inktomi offers routers and load balancers from Alteon WebSystems and Foundry Networks bundled together with Inktomi's Traffic Server caching software. Cisco Systems and Lucent Technologies also offer high-end caching appliances with proprietary operating system kernels tuned for top performance in this application.

A relatively new approach is called predictive client-side caching and involves configuring a plug-in for client browsers that determines what kinds of content the client accesses and then attempts to preload such content during idle times so that when the client requests it the content is already in the browser cache. Blueflame, a product from Fireclick, is one example of predictive client-side caching technology. Fireclick also has a hosted version of this application called Netflame.

Packeteer has a product called AppCelera Internet Content Accelerator (ICX) that boosts performance by adapting requested content to the type of browser requesting it and by compressing content to make better utilization of available bandwidth.

Issues

Caching of dynamic Web content presents an ever-greater challenge as more and more Web sites move away from static informational content to deploying database-driven e-commerce Web applications. Dynamic Web pages are generated from databases in response to user queries and often include some form of personalization as well. Dynamic content cannot be cached the way static content can, but a number of vendors have come up with various methods for improving the performance of dynamic Web applications by using caching. For example, the components of a Web application can be cached for reuse across multiple user sessions. Another approach is to dynamically monitor the configuration of Web applications to better manage stale cache content. Vendors of dynamic caching systems include Xcache Technologies, Chutney Technologies, and SpiderSoftware. NetScaler offers a caching device that routes requests for static content to traditional cache servers while multiplexing requests for dynamic content over persistent connections with Web servers to improve performance.

Notes

Caching in a general sense is used in various ways by operating systems, applications, and network devices to improve performance by providing temporary storage of information that needs to be quickly accessed. Some common examples include

- The file system cache for the Microsoft Windows 2000 operating system, which speeds up file access from hard disk drives
- Offline Files in Windows 2000, which allows users to browse network file system content when disconnected from the network
- Domain Name System (DNS) cache for caching recently resolved host names on a name server, which speeds up the resolution of host names for the DNS on the Internet

C

- Address Resolution Protocol (ARP) cache on a host connected to an IP internetwork, which is used for caching IP addresses that have recently been resolved into MAC addresses, thus speeding up network communications between hosts
- Microsoft Internet Security and Acceleration (ISA) Server, which allows Web content obtained from the Internet to be cached locally for faster access and reduction of WAN link congestion
- Caching of open database connectivity (ODBC) connections for improved access to Microsoft SQL Server databases for Active Server Pages (ASP) applications written for Microsoft Internet Information Services (IIS)

Caching Array Routing Protocol (CARP)

A protocol developed by Microsoft Corporation that allows multiple proxy servers to be arrayed as a single logical cache for distributed content caching.

Overview

Caching Array Routing Protocol (CARP) is implemented as a series of algorithms that are applied on top of Hypertext Transfer Protocol (HTTP). CARP allows a Web browser or downstream proxy server to determine exactly where in the proxy array the information for a requested Uniform Resource Locator (URL) is stored.

CARP enables proxy servers to be tracked through an array membership list that is automatically updated using a Time to Live (TTL) countdown function. This function regularly checks for active proxy servers in the array. CARP uses hash functions and combines the hash value of each requested URL with each proxy server. The URL/proxy server hash with the highest value becomes the owner of the information cached. This results in a deterministic location for all cached information in the array, which enables a Web browser or

downstream proxy server to know exactly where a requested URL is locally stored or where it will be located after it has been cached. The hash functions result in cached information being statistically distributed (load balanced) across the array. Using hashing means that massive location tables for cached information need not be maintained—the Web browser simply runs the same hashing function on the object to locate where it is cached.

Advantages and Disadvantages

CARP provides two main benefits:

- It saves network bandwidth by avoiding the query messaging between proxy servers that occurs with conventional Internet Cache Protocol (ICP) networks.
- It eliminates the duplication of content that occurs when proxy servers are grouped in arrays, resulting in faster response times and more efficient use of server resources.

caching-only name server

A name server in the Domain Name System (DNS) that can resolve name lookup requests but does not maintain its own local DNS database or zone file of resource records.

Overview

Caching-only name servers do not have their own DNS databases. Instead, they resolve name lookup requests from resolvers by making iterative queries to other name servers. When the responses to these queries are received, the caching-only name server caches them, in case another resolver issues the same request within a short period of time.

A caching-only name server is not authoritative for any particular DNS domain. It can look up names that are inside or outside its own zone.

Notes

Caching-only name servers are not the only kind of name server that performs caching of resolved queries. For example, primary name servers also cache name

lookups that they perform. This caching generally improves the primary name server's response to name lookup requests from resolvers. Caching-only name servers are distinguished by the fact that they perform only one function: issuing iterative queries to other name servers and then caching the results.

Caching-only name servers provide support for primary and secondary name servers in environments where name lookup traffic is heavy. Using caching-only name servers where possible also reduces the overhead of zone transfers between name servers on a network.

caching service provider (CSP)

A company that maintains caching servers that speed the transfer of information across the Internet's infrastructure and offers managed access to these servers for a fee.

Overview

Many companies think that if they host their Web site at an Internet service provider (ISP) or at a major Web hosting company, the site will always be accessible from anywhere on the Internet, but this is not necessarily true. Traffic congestion can cause access to a Web server to be slow and unreliable from various parts of the Internet at various times of the day, and equipment failures (such as routes going down at Internet peering points) can make a server completely inaccessible to certain portions of the Internet until the problem is fixed. ("Peering" means two ISPs or other providers passing traffic between each other's customers.)

One solution is to mirror (replicate) your Web server at various points around the globe so that a copy of your site is relatively close to any location on the Internet. For companies with a global presence, this is a fairly simple solution to implement, but most companies do not have the presence or the resources to implement global mirroring. A better solution might be to use the services of a caching service provider (CSP), which maintains cached

copies of your Web site at various points in the Internet's infrastructure and provides tools for managing and load balancing the content to handle traffic spikes that occur at certain times of the day or year.

CSPs maintain data centers around the world with caching server farms that have high-speed connections to the Internet's backbone. These caching servers are usually designed to cache Web content and often support features such as content management and proxying. Caching servers can also be used within the corporate network to speed access to large, distributed corporate intranets.

CAL

Stands for client access license, a license that grants a client machine access to a Microsoft BackOffice product running on a network of computers.

See: *client access license (CAL)*

callback

A security feature for remote access servers.

Overview

Callback provides an extra layer of security for users dialing in to a remote access server. When callback is configured, the client software dials in to a remote access server and has the user's credentials authenticated. The remote access server then disconnects the client and calls the client back at a previously specified phone number. Callback might be configured in the following ways:

- To ensure that the user matches his or her credentials by verifying the telephone location
- For accounting reasons—for example, to charge the phone bill to the remote access server instead of to the client

C

Callback. How callback is used in remote access.

Callback is an optional feature supported by the Routing and Remote Access service of Microsoft Windows 2000 and Windows .NET Server. Note that in Windows 2000 and Windows .NET Server, the phone number specified for callback is called the Caller ID number.

Callback Control Protocol (CBCP)

A protocol that enables callback for establishing Point-to-Point Protocol (PPP) connections.

Overview

The Callback Control Protocol (CBCP) is part of Microsoft Corporation's implementation of the Point-to-Point Protocol (PPP). CBCP makes it possible for a PPP server to call back the remote dial-in client to complete initiation of a PPP dial-up session. Callback is a useful security feature for ensuring that dial-in clients are authentic.

Implementation

The CBCP is used during the third phase of establishing a PPP connection. After the PPP link is established using the Link Control Protocol (LCP) and the user's credentials are authenticated using Microsoft Challenge Handshake Authentication Protocol (MS-CHAP) or some other authentication protocol supported by the client, the network access server (NAS) at the PPP service provider can optionally initiate a PPP callback control phase, provided that callback is configured on the server. The NAS and the PPP clients both disconnect from the PPP link, and the NAS calls the client back using the specified callback phone number. If the client responds, the link is reestablished; no further authentication is needed, and

compatible network protocols are negotiated so that data transmission can begin.

campus area network (CAN)

A group of connected local area networks (LANs) on a campus.

Overview

A campus area network (CAN) is intermediate in size between a LAN, which typically resides in a single room or building, and a metropolitan area network (MAN), which spans a city or metropolitan area. CANs exist on university campuses, in industrial parks, and in similar collections of buildings under a single administrative authority.

Implementation

CANs are typically built in hierarchical fashion starting from the top or inside with a core network (usually a collapsed backbone), a distribution network (routers or switches in different buildings), an access network (a collection of hubs and switches within wiring closets on each floor of the buildings), and finally end-user stations.

Stands for carrierless amplitude and phase modulation, a line coding scheme in which data is modulated using a single carrier frequency.

capture

A collection of frames gathered from network traffic by a sniffer.

Overview

You can use packet-sniffing software such as Microsoft Network Monitor (which is included in Microsoft Systems Management Server and in a simplified form in Microsoft Windows 2000, Windows XP, and Windows .NET Server) for capturing all kinds of traffic on the network. This captured traffic is displayed in the capture window as a variety of statistics and details about the nature of the traffic. Additional windows can display details about individual packets that have been captured.

Capturing network traffic is a common troubleshooting technique on enterprise-level networks. Captures can show whether services such as Dynamic Host Configuration Protocol (DHCP), Windows Internet Name Service (WINS), Domain Name System (DNS), and other common network services are performing properly. Captures can also isolate servers that are generating excessive network traffic because of failed hardware. Captures can even be used to detect unauthorized traffic initiated by hackers and disgruntled employees and to profile network traffic for planning purposes.

See Also: *capture window, sniffing*

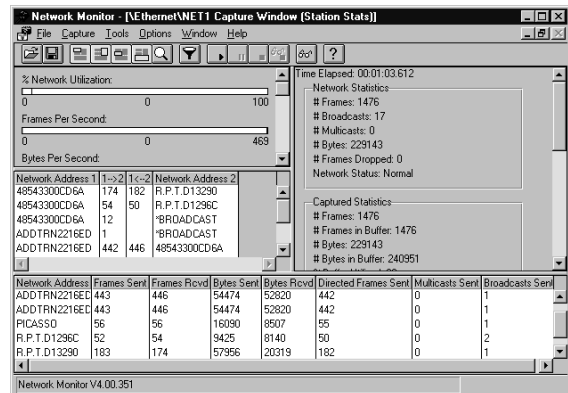

capture window

In Microsoft Network Monitor, the window that displays the statistics about the frames being captured on a network.

Overview

The capture window displays four kinds of real-time statistics concerning the traffic that an administrator captures using Network Monitor:

- **Graph statistics:** A graphical representation of current network activity that shows the percent of network utilization, frames captured per second, bytes captured per second, and broadcasts or multicasts captured per second
- **Session statistics:** Information about current sessions between computers on the network, showing which hosts have sent packets to each other
- **Station statistics:** Information about various stations involved in sending or receiving packets, showing how many of each type of packet they have sent or received
- **Total statistics:** Summary statistics about network activity since the capture began, including the number of frames, bytes, and frames dropped during the capture

Capture window. The capture window in Network Monitor, which is included with Microsoft Systems Management Server.

You can toggle these various windowpanes on and off during a capture to focus on statistics of interest.

Carnivore

An Internet surveillance system developed by the FBI (Federal Bureau of Investigation).

C

Overview

Carnivore was designed to help the FBI collect evidence to convict terrorists, drug smugglers, and hackers. Carnivore is a self-contained “black-box” Internet Protocol (IP) traffic filtering system that sniffs network traffic to find e-mail and other traffic that contains evidence of criminal activity.

Implementation

To use Carnivore, the FBI first obtains a court order to capture specific types of Internet traffic that may contain evidence of criminal wrongdoing by parties under consideration. The FBI then brings the Carnivore system to an Internet service provider (ISP) and connects the system to the backbone switches of the ISP’s network. Carnivore then monitors all traffic through the ISP, capturing only such traffic as matches the filter conditions established in the court order (this is called minimization—Carnivore does not snoop all traffic indiscriminately). For example, Carnivore might filter all messages coming from or going to a specific IP address block or having a certain keyword in the Subject line.

carrier

A company that provides various kinds of telecommunication services to its customers.

Overview

A carrier provisions telecommunication services to the customer premises. These services include voice transmission, data transmission over analog modems, Integrated Services Digital Network (ISDN), digital subscriber line (DSL), frame relay, and anything else the carrier’s equipment supports. There are two basic kinds of carriers: LECs and IXC.

A local exchange carrier (LEC) is a company that provides access to both local and long-distance telephone services through the local loop connecting the telco’s central office (CO) with the customer premises. In the United States, LECs are typically one of two kinds:

- Local phone companies, now usually called Incumbent Local Exchange Carriers (ILECs) but sometimes called Regional Bell Operating Companies (RBOCs).
- Competitive Local Exchange Carriers (CLECs), a new breed of LEC that has arisen in response to the Telecommunications Act of 1996. CLECs that offer primarily DSL voice/data services are often called DSL carriers.

An inter-exchange carrier (IXC), on the other hand, is a company that provides long-distance services only. IXCs own their own telecommunication facilities and provide long-distance services between LECs located in different toll-free areas. The big three in the IXC arena in order of size are AT&T, MCI WorldCom, and Sprint Corporation.

All long-haul carriers in the United States use Synchronous Optical Network (SONET) or ATM (Asynchronous Transfer Mode)/SONET as their backbone transport, and most local telcos use ATM in their own backbone networks also. Some LECs are also deploying Gigabit Ethernet (GbE) as an alternative to ATM for metropolitan area networks (MANs) that can bring GbE ports directly to the edge of corporate networks, providing end-to-end Ethernet connectivity for corporate wide area networks (WANs).

Outside the United States, most carriers use Synchronous Digital Hierarchy (SDH), essentially a variant of SONET.

Implementation

Almost all carriers rely on ATM as their underlying backbone transport and use this backbone to provision local and long-distance voice services, Internet access over DSL, leased-line WAN links, and other services. A large portion of the backbone of most long-haul carriers is currently at or near OC-48, providing maximum throughput of 2.488 gigabits per second (Gbps), but

these backbone fiber connections are constantly being upgraded to support higher speeds such as OC-192 and OC-768.

Carriers usually house their high-speed switching equipment in large buildings called colocation centers. These centers have this name because under the Telecommunications Act of 1996, competitive local exchange carriers (CLECs) are allowed to lease space within carrier facilities for locating their own switching equipment. Another name for these centers is “data centers,” and they are usually huge nondescript buildings that typically occupy hundreds of thousands of square feet. Sometimes several floors of existing buildings are used for data centers, but the trend is to build new centers to ensure that the highest standards of fire safety and security are used.

Marketplace

The global carrier market has become complex over the last decade, with traditional incumbent telcos in the United States and Post, Telegraph, and Telephone (PTT) companies in Europe being challenged on all sides by newcomers to the game. International carriers can be classified in different types, including

- **Incumbents:** These are traditional or established carriers such as public telephone companies, long distance companies, and PTTs in Europe.
- **Cross-border infrastructure owners:** These are companies that own the international lines carrying voice and data between countries, regions, and continents.
- **Resellers:** This includes companies reselling both local loop and long haul services purchased wholesale from other carriers.

To complicate things further, many large national carriers are constantly making efforts to expand into the international market by acquiring, or merging with, other carriers, upgrading their core equipment to provision new high-speed data services, while relegating some existing services to the legacy domain and trying to cope with the ever-exploding amounts of Internet bandwidth demanded by their customers. Because of the state of

flux of the global telecommunications carrier market, the enterprise architect’s dream of simple, seamless, global WAN connectivity remains a complicated reality of tariffs, interoperability issues, and politics.

carrierless amplitude and phase modulation (CAP)

A line coding scheme in which data is modulated using a single carrier frequency.

Overview

Carrierless amplitude and phase modulation (CAP) is used for transmission of voice information over a phone line. The transmission is considered “carrierless” because the carrier is suppressed before transmission and is reconstructed at the receiver. CAP is algorithmically similar to the quadrature amplitude modulation (QAM) line coding scheme, which encodes bits as discrete phase and amplitude changes, but it has different transmission characteristics.

Notes

Some competitive local exchange carriers (CLECs) deploy Asymmetric Digital Subscriber Line (ADSL) using CAP as the encoding method, but results of some independent tests suggest that CAP-encoded ADSL lines might cause spectral interference with proximate T1 lines and Integrated Services Digital Network (ISDN) circuits, resulting in bit errors that can reduce throughput. However, these tests might be misleading because of the limited number of ADSL circuits currently deployed by CLECs. Check with your carrier before signing up for ADSL services to get the latest information about this issue.

Such interference is not a problem with symmetric digital subscriber line (SDSL) technologies, which use the 2B1Q encoding scheme. Furthermore, ADSL deployed by incumbent local exchange carriers (ILECs) uses discrete multitone (DMT) technology, which does not produce the same degree of spectral interference as CAP.

C

Competitive local exchange carriers generally do not use DMT for ADSL because they must deal with the copper local loop, which effectively supports DMT only about half the time but can support CAP about 85 percent of the time. Furthermore, DMT has been adopted as the standard for ADSL by both the American National Standards Institute (ANSI) and the International Telecommunication Union (ITU).

Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA)

The media access control method used by AppleTalk.

Overview

Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA) is a type of media access control method for placing signals on baseband transmission networks. Because baseband networks can carry only one data signal at a time, there must be some way of controlling which station has access to the media at any given time. CSMA/CA is one such control method.

Uses

CSMA/CA is the standard access method for AppleTalk networks based on LocalTalk. LocalTalk is a legacy network media technology that specifies the proprietary cabling components of the original AppleTalk networking architecture. LocalTalk uses a bus topology or tree topology that supports up to 32 stations on a network.

Implementation

In networking technologies that use CSMA/CA as their access method, stations announce their intention to transmit before they actually transmit their data onto the network media. Each station “listens” constantly to the wire for these announcements, and if it hears one, it avoids transmitting its own data. In other words, on a CSMA/CA network, stations try to avoid collisions with signals generated from other stations. The extra signaling generated by CSMA/CA makes it a slower access method than the Carrier Sense Multiple Access

with Collision Detection (CSMA/CD) method used in Ethernet networking.

Carrier Sense Multiple Access with Collision Detection (CSMA/CD)

The media access control method used by Ethernet.

Overview

Carrier Sense Multiple Access with Collision Detection (CSMA/CD) is a type of media access control method developed by Xerox Corporation in the 1970s for placing signals on baseband transmission networks.

Because baseband networks can carry only one data signal at a time, there must be some way of controlling which station has access to the media at any given time. CSMA/CD is one such control method.

Implementation

In networking technologies that use CSMA/CD as their access method, a station first “listens” to the network media to make sure there is no signal already present from another station before it tries to place its own signal on the media. If a carrier signal is detected on the media, which indicates that a station is currently transmitting a signal, no other station can initiate a transmission until the carrier stops. If no carrier is detected, any station can transmit a signal.

If two stations listen to the wire and detect no carrier signal, they may both decide to send signals simultaneously. If this happens, a collision occurs between the two signals generated. Next, both stations detect the collision and stop transmitting their signals immediately, sending out a jamming signal that informs all other stations on the network that a collision has occurred and that they should not transmit. Meanwhile, the two stations whose signals created the collision cease transmitting and wait random intervals of time (usually a few milliseconds) before attempting to retransmit.

Issues

CSMA/CD is known as a contention method because computers contend for the chance to transmit data onto the network media. CSMA/CD is the standard access method for Ethernet networks. This method has two main drawbacks:

- Only a relatively small number of computers can exist within any one collision domain. More computers will produce more collisions and slow overall network traffic.
- CSMA/CD is not reliable beyond a distance of 1.5 miles (2.5 kilometers) because of signal attenuation.

Notes

The designation CSMA/CD derives from the following:

- CS means that stations first sense a carrier present on the media before transmitting their own signals.
- MA means that multiple stations can access the network media.
- CD means that if a collision is detected because of multiple simultaneous transmission of signals, the stations that are transmitting signals stop, and then retransmit a short time later.

carrier signal

An alternating electromagnetic signal with a steady frequency upon which information is superimposed by some form of modulation.

Overview

The specific frequency at which a carrier signal runs is called the carrier frequency and is measured in hertz (Hz). The modulation of the carrier signal enables information such as voice or data traffic to be integrated into the carrier signal. The carrier signal thus “carries” the voice or data information using modulation technologies.

The type of modulation used in digital communication systems depends on whether the underlying carrier signal is analog or digital. For example, in digital radio or microwave communication, some form of digital-analog modulation, such as frequency-shift keying (FSK), is used to impose the digital (binary) information on the analog carrier wave. On the other hand, in Ethernet networking, a digital-digital encoding scheme called Manchester coding is used to enable the digital signal to carry binary 1s and 0s.

In Ethernet networks, the carrier signal plays an important role in the media access control method that Ethernet uses, namely the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) method.

cascading style sheets (CSS)

A method for giving Web developers more control over how the pages of a Web site will look when displayed on a Web browser.

Overview

Cascading style sheets (CSS) is a standard from the World Wide Web Consortium (W3C) that gives Web developers control over design elements such as fonts and font sizes and allows two-dimensional overlapping and exact positioning of page elements. The CSS standard also makes it easier to globally change the style and appearance of a Web site without having to change elements on every page.

Implementation

Hypertext Markup Language (HTML) was designed for logical communication of linked information without much regard for its style or format, and it was not designed to provide a high degree of control over how that information is laid out on a page. Using CSS, a Web developer can control the appearance of an entire Web site, or a portion of it, using a single HTML page

C

called a style sheet. The genius of CSS is that it separates the content of the page (formatted in HTML) from the page layout (defined in the style sheet using CSS).

Style sheets define the functions of different HTML tags on your site's Web pages and allow you to make global changes to your site's style by changing a single entry on a style sheet. Web pages then link to style sheets using a <LINK> tag.

For example, you can use a style sheet to define the <H1> tag as representing green, 18-point, Arial font text, and you can then apply this style to the entire site or a portion of it. Cascading style sheets involve the operation of several levels of style sheets that provide control over how an element on an HTML document is placed. CSS applies these settings in the following order:

- The STYLE attribute in the object's tag
- The STYLE element between the <TITLE> and <BODY> tags that specifies the style sheet to be used
- The settings of the browser accessing the page and its default style sheet

Issues

The main factor that has prevented CSS from being widely implemented on most Web sites is that neither Microsoft Internet Explorer nor Netscape Navigator fully supports all aspects of the CSS standard. Thus, a CSS-enabled site may look one way in Internet Explorer and another way in Netscape, and neither may be what the site designer intended. One Web browser that fully implements the CSS standard is Opera, developed by Hakon Lie, who has been involved in the W3C.

catalog

The top-level organizational structure for the Indexing service in Microsoft Windows 2000, Windows XP, and Windows .NET Server.

Overview

The catalog contains the master index and other persistent indexes. The Index Server catalog is located by default in the directory %systemdrive%\inetpub\catalog.wci, but this can be overridden during installation. The maximum size of the catalog for Index Server is 40 percent of the size of the documents being indexed (the corpus), so it is important when installing Index Server to locate the catalog on a drive with sufficient free space. For example, if you will be indexing 10 gigabytes (GB) of documents, you will need about 4 GB of space for locating your catalog.

Notes

An Indexing service query can span only one catalog at a time, so do not create multiple catalogs unless you want to completely separate the indexing of their documents—for example, if you are hosting Web sites for multiple companies on your server.

If you are hosting more than one virtual server on a Microsoft Internet Information Services (IIS) machine, and these virtual servers represent different companies, you might want to create multiple catalogs for the Indexing service, one for each virtual server. Each catalog will then be used for indexing a specific virtual server, and queries based on a catalog will return only results for content on the associated virtual server.

Category 1 (Cat1) cabling

The lowest grade of unshielded twisted-pair (UTP) cabling.

Overview

Category 1 (Cat1) cabling was designed to support analog voice communication only. Cat1 cabling was used prior to 1983 for wiring installations of analog telephone systems, otherwise known as the Plain Old Telephone Service (POTS). The electrical characteristics of Cat1 cabling make it unsuitable for computer networking purposes, and it is never installed as premise wiring for structured cabling installations. Instead, all premise wiring should use either Category 3 (Cat3) cabling, Category 4 (Cat4) cabling, or Category 5 (Cat5) cabling, with Cat5 or enhanced Category 5 (Cat5e) cabling preferred for all new installations.

See Also: cabling, premise cabling, structured wiring

Category 2 (Cat2) cabling

The second-lowest grade of unshielded twisted-pair (UTP) cabling.

Overview

Category 2 (Cat2) cabling was designed to support digital voice and data communication. Cat2 cabling was capable of data transmissions up to 4 megabits per second (Mbps). It was used primarily in the installation of

premise wiring for legacy Token Ring networks from IBM. The electrical characteristics of Cat2 cabling make it unsuitable for most networking purposes today, thus it is no longer installed as premise wiring. Instead, all premise wiring today should use only Category 3 (Cat3) cabling, Category 4 (Cat4) cabling, or Category 5 (Cat5) cabling, with Cat5 or enhanced Category 5 (Cat5e) cabling preferred for all new installations.

See Also: cabling, premise cabling, structured wiring

Category 3 (Cat3) cabling

The third-lowest grade of unshielded twisted-pair (UTP) cabling.

Overview

Category 3 (Cat3) cabling was designed to support digital voice and data communication at speeds up to 10 megabits per second (Mbps). It uses 24-gauge copper wires in a configuration of four twisted-pairs enclosed in a protective insulating sheath. Cat3 cabling is the lowest grade of UTP cabling that can support standard 10BaseT types of Ethernet networks and was often used for legacy 4-Mbps Token Ring installations.

Cat3 cabling still has a significant installed base in older buildings, and for basic 10BaseT Ethernet purposes, it is often cheaper to use existing Cat3 cabling than to upgrade to Category 5 (Cat5). Installing higher-grade cabling for backbone cabling in vertical rises and elevator shafts can extend the life of work areas that still use Cat3 cabling. However, if greater speeds are required at users' workstations, the best solution is to rewire the work areas using Cat5 cabling or enhanced Category 5 (Cat5e) cabling.

The following table summarizes the electrical characteristics of Cat3 cabling at different frequencies, which correspond to different data transmission speeds. Note that attenuation increases with frequency, while near-end crosstalk (NEXT) decreases.

Category 4 (Cat4) cabling

The grade of unshielded twisted-pair (UTP) cabling just below standard Category 5 (Cat5) cabling.

Overview

Category 4 (Cat4) cabling was designed to support digital voice and data communication at speeds up to 16 megabits per second (Mbps). It uses 22-gauge or 24-gauge copper wires in a configuration of four twisted-pairs enclosed in a protective insulating sheath. Cat4 cabling can support standard 10BaseT types of Ethernet networks. It was also commonly used in older 16-Mbps Token Ring installations.

Cat4 cabling still has some installed base in older buildings where it is often cheaper to use the existing cabling than to upgrade to newer grades. Installing higher-grade cabling for backbone cabling in vertical rises and elevator shafts can extend the life of work areas that still use Cat4 cabling. However, if greater speeds are required at users' workstations, the best solution is to rewire the work areas using Cat5 cabling or enhanced Category 5 (Cat5e) cabling.

The following table summarizes the electrical characteristics of Cat4 cabling at different frequencies, which correspond to different data transmission speeds. Note that attenuation increases with frequency, while near-end crosstalk (NEXT) decreases.

Category 5 (Cat5) cabling

The most common grade of unshielded twisted-pair (UTP) cabling used for structured wiring in commercial buildings.

Overview

Category 5 (Cat5) cabling was designed to support digital voice and data communication at speeds up to 100 megabits per second (Mbps). It uses 22-gauge or 24-gauge copper wires in a configuration of four twisted-pairs enclosed in a protective insulating sheath. It is still the highest official grade of UTP cabling currently recognized by the Electronic Industries Alliance (EIA) and Telecommunications Industry Association (TIA), although proposals have been made for higher Category 6 (Cat6) and Category 7 (Cat7) grades.

Cat5 cabling is the standard grade of UTP cabling for common networking architectures including 10BaseT Ethernet, Fast Ethernet, and 1000BaseT Gigabit Ethernet (GbE) over copper. Cat5 cabling typically makes up over 80 percent of the wiring in today's corporate network. Its continuing popularity in high-speed networks is because fiber-optic cabling is still about twice as expensive to deploy as Cat5 cabling. Because of its superior electrical characteristics, Cat5 cabling is recommended for all new structured wiring installations as well as for upgrading existing premise wiring to support higher-speed networks.

The following table summarizes the electrical characteristics of Cat5 cabling at different frequencies, which correspond to different data transmission speeds. Note that attenuation increases with frequency, while near-end crosstalk (NEXT) decreases.

Cat5 Cabling Characteristics

<i>Characteristic</i>	<i>Value at 10 MHz</i>	<i>Value at 100 MHz</i>
Attenuation	20 decibels (dB)/1000 feet	22 dB/1000 feet
NEXT	47 dB/1000 feet	32.3 dB/1000 feet
Resistance	28.6 ohms/1000 feet	28.6 ohms/1000 feet
Impedance	100 ohms ($\pm 15\%$)	100 ohms ($\pm 15\%$)
Capacitance	18 pF/feet	18 pF/feet
Structural return loss	16 dB	16 dB
Delay skew	45 nanoseconds (ns)/100 meters	45 ns/100 meters

Marketplace

There are a vast number of different brands of Cat5 cabling on the market today. One estimate is that there are over 150 different vendors of such cabling. Not all Cat5 cabling is alike, and before undertaking a costly large-scale deployment of structured wiring, the enterprise architect should carefully investigate and compare the different brands.

Notes

For typical installations of Ethernet and Fast Ethernet, Cat5 cables in work areas should be no more than 300 feet (90 meters) long, and Cat5 patch cords should be no longer than 33 feet (10 meters). Check the Ethernet specifications for exact lengths permitted.

Many vendors offer an enhanced Cat5 (Cat5e) cabling grade with electrical characteristics exceeding those of standard Cat5. Cat5e cabling typically supports data transmission up to frequencies of 350 MHz, and new standards are under development to allow even higher data transmission frequencies. Cat5e networking is recommended for Gigabit Ethernet (GbE) over copper, but properly installed Cat5 cabling should work in most GbE setups. For best performance of GbE networks, however, use Cat5e or Cat 6 cabling whenever possible.

There is widespread agreement that Cat5 cabling will not be able to support networks beyond GbE, such as the 10 GbE architecture currently under development. Such ultra-high speed networks will likely work only with fiber and will not support copper.

Category 6 (Cat6) cabling

The proposed next step up from enhanced Category 5 cabling (Cat5e).

Overview

Category 6 (Cat6) is a proposed Electronic Industries Association/Telecommunications Industry Association (EIA/TIA) cabling standard that represents the next step up from Cat5 and Cat5e cabling. The following table shows the current draft standard for Cat6 cabling characteristics.

Proposed Cat6 Cabling Characteristics

<i>Characteristic</i>	<i>Value at 250 MHz</i>
Attenuation	19.9 decibels (dB)/1000 feet
NEXT	44.3 dB/1000 feet
Impedance	100 ohms ($\pm 15\%$)
Return loss	20.1 dB
Delay skew	45 nanoseconds (ns)/100 meters
PS-NEXT	42.3 dB

Implementation

Great care must be taken when installing Cat6 cabling in order to have it achieve its design goals because poorly installed Cat6 cabling may offer only Cat5 performance. To get best performance out of Cat6 cabling for high-speed networking, be sure to follow the following guidelines:

- Buy cabling that has a definite spline separating the cables to reduce crosstalk.
- Make sure twists in wires are kept flush with connections at all termination blocks to avoid return-loss issues.
- Liberally use a hook and loop fastener, such as Velcro, to prevent cable from becoming excessively crimped.

C

Issues

Despite the formation in 1999 of a TIA task force to develop an official standard for a proposed Cat6 cabling, this unshielded twisted-pair (UTP) cabling standard remains to be ratified. The inherent engineering difficulties of standardizing cabling transmission characteristics for transmissions at 250 MHz and above, coupled with the fact that many cabling vendors have released their own “Category 6 or better” cabling, has led to some confusion in the marketplace. A factor that has slowed the development of Cat6 standards was the successful implementation of 1000BaseT Gigabit Ethernet (GbE) over Cat5 cabling, which relaxed the immediate need for a higher Cat6 class of cable and slowed the momentum of the Cat6 standards process. Cat6 thus currently appears as a solution in search of a problem, and the emergence of 10 Gigabit Ethernet (10 GbE) may have little impact on this situation because 10 GbE is envisioned as a fiber-only architecture.

At present Cat6 cabling solutions are essentially “channel solutions,” meaning that their successful implementation depends on purchasing cabling components (such as cabling, patch panels, jacks, and wall plates) from a single vendor. Until an official Cat6 standard emerges, networking architects are recommended to use such channel solutions from a singling cabling vendor. In fact, some believe that “mix and match” cabling solutions for Cat6 will never be achieved due to the careful tuning of components that must be performed to make such systems work.

Notes

Existing cable testing equipment will not be able to evaluate Cat6 cabling because Cat6 not only includes additional parameters that must be measured but also specifies at least 10 dB greater precision in measuring existing cabling transmission characteristics over that achieved by Cat5e test equipment.

Some experts believe that it may be possible in the future to run 10 gigabits per second (Gbps) over Cat6 cabling at distances up to 330 feet (100 meters). If this is the case, then Cat6 cabling may well serve as an alternate infrastructure solution to fiber for the emerging 10 GbE standard. Such uses of Cat6 cabling are likely to be

restricted to niche applications such as switch-switch and switch-server interconnects and within some types of storage area networks (SANs).

Another name for the proposed Cat6 cabling standard is Class E.

Category 7 (Cat7) cabling

A still-hypothetical next step up from the proposed Category 6 (Cat6) cabling.

Overview

There is as yet no official Telecommunications Industry Association (TIA) standard for unshielded twisted-pair (UTP) cabling above Cat6, and Cat6 itself is still under consideration and has not been ratified as a standard. Nevertheless, many cabling vendors are offering “Category 7 cabling solutions” that exceed the specifications of Cat6. Such marketing should be taken with a grain of salt, as they do not represent true Cat7 standards, but such “channel solutions” involving cabling system elements purchased from a single vendor can provide significantly better performance than standard enhanced Category 5 (Cat5e) cabling. It is likely that when a true Cat7 standard emerges, it may require the replacement of the ubiquitous RJ-45 connector, which is a weak point in the transmission architecture for UTP cabling. Unfortunately, this means that existing networking equipment such as switches and routers may not be able to support Cat7.

While the Electronic Industries Association/Telecommunications Industry Association (EIA/TIA) has currently abandoned efforts to standardize Cat7, standards efforts are underway on the international scene through the efforts of the International Standards Organization (ISO) and International Electrotechnical Commission (IEC).

Another name for proposed Cat7 cabling is Class F cabling.

CDF file

Text files used for creating Active Channels, Active Desktop items, and channel screen savers for managed webcasting of content to users’ desktops.

Overview

CDF files are based on the Channel Definition Format (CDF) standard. CDF files provide a mechanism for allowing users to select the content they want to download from a Web site, and they let administrators schedule content for delivery to users’ desktops.

CDF files are used to convert existing Web sites into Active Channels without the need to change the existing site in any way. You simply create a CDF file using a text editor such as Microsoft Notepad and include it in your site. This will allow the content of the site to be webcast to users’ browsers. The CDF file must be saved with the extension .cdf, and a link on your site should point to this file so that users can subscribe to the channel.

A typical CDF file defines a channel hierarchy for the different Web sites making up the Active Channel. This channel hierarchy contains a table of contents for webcasting the content and consists of a top-level channel, subchannels, and actual content items (Web pages). The simplest format for a CDF file is a list of Uniform Resource Locators (URLs) that point to specific Web pages in the site. More advanced CDF files can contain information such as the following:

- A map of the hierarchical structure of the URLs in the Web site
- Logical groupings of different content items within a site that can differ from the observable link structure of the site itself
- The title of each referenced Web page and a brief abstract of its contents
- Information controlling the scheduling of content updates

The syntax of advanced CDF file items is based on the Extensible Markup Language (XML), an open specification that provides extensibility to standard Hypertext Markup Language (HTML) files. More than one CDF

C

file can be created for a site, allowing users to subscribe to information in different fashions. For example, a news site can have separate CDF files for news, sports, and weather subscriptions.

Notes

For specific information on the syntax of CDF files and how to create them, refer to the Microsoft Internet Client software development kit (SDK).

Channels in Active Channel enable personalized delivery of Web content using Web applications designed for Internet Information Service (IIS) for Windows 2000. Active Server Pages (ASP) can be used for dynamically generating personalized CDF files for users. Cookies can also be used for dynamically generating customized CDF files for users. These CDF files can be customized on the basis of preferences that a user specifies on an HTML form prior to subscribing to the channel.

CDMA2000

A proposed third-generation (3G) upgrade for existing Code Division Multiple Access (CDMA) cellular telephone systems.

Overview

CDMA2000 was developed by the Telecommunications Industry Association (TIA) and is part of the International Mobile Telecommunications 2000 (IMT-2000)

initiative of the International Telecommunication Union (ITU). CDMA2000 will boost the bandwidth of existing cdmaOne cellular systems to 2 megabits per second (Mbps), making global broadband wireless communications a reality.

Because the proposed CDMA2000 upgrade includes only a small portion of the overall wireless communication market, the IMT-2000 initiative also includes proposed upgrades to Time Division Multiple Access (TDMA) systems such as Global System for Mobile Communications (GSM). A competing upgrade for TDMA systems is General Packet Radio Service (GPRS), which is closer to implementation than CDMA2000 and might therefore win more initial support than CDMA2000.

The term *CDMA2000 1x* is commonly used to describe various interim CDMA2000 systems that use existing IS-95a base stations to provide 2.5G cellular services. CDMA2000 1x systems expect to achieve data transmission speeds of between 144 kilobits per second (Kbps) and 307 Kbps and are therefore classed as 2.5G cellular services instead of the much faster 3G services envisioned by IMT-2000. The proposed 3G system Wideband CDMA (W-CDMA) is comparable to CDMA2000 2x, meaning the 3G version of CDMA2000.

The CDMA Development Group is also promoting a different CDMA2000 upgrade called High Data Rate (HDR) CDMA2000 1x. This platform is based on the American National Standards Institute (ANSI) IS-95c standard and is viewed as an alternative upgrade path from CDMAone toward 3G. It involves a hardware upgrade using chipsets produced by QUALCOMM (the originators of CDMA) and may provide data speeds up to 2.4 Mbps, even better than the 2 Mbps speeds anticipated by W-CDMA. In some respects HDR may be superior to W-CDMA, the 3G version of CDMA being proposed by the ITU in its IMT-2000 initiative. Specifically, while W-CDMA is expected to provide 2 Mbps service only for stationary users, and much slower speeds for mobile and roaming users, HDR is intended to provide the same 2.4 Mbps speed for all users whether mobile or stationary. However, W-CDMA has

the advantage of being a proposed standard for implementing compatible systems throughout the world. Only time will tell which system achieves market dominance.

CD-ROM File System (CDFS)

A file system designed for read-only CD-ROM media.

Overview

CD-ROM File System (CDFS) is an International Organization for Standardization (ISO) standard (ISO 9660) for a read-only formatting standard for CD-ROM media. CDFS provides the same kind of file and directory management for CD-ROM devices that the file allocation table (FAT) and NTFS file systems (NTFS) do for hard disks.

CDFS is implemented on the Microsoft Windows 95, Windows 98, Windows Millennium Edition (Me), Windows NT, Windows 2000, Windows XP, and Windows .NET Server platforms. On 32-bit Windows systems, CDFS uses a 32-bit protected-mode driver that replaces the 16-bit real-mode Microsoft CD-ROM Extension (MSCDEX) driver that was used in the legacy 16-bit Windows and MS-DOS operating system platforms. In Windows 95 and Windows 98, the file system driver that supports CDFS is called Cdfs.vxd, and in Windows NT, Windows 2000, Windows XP, and Windows .NET Server, it is called Cdfs.sys.

CDFS is optimized for reading compact discs that have a standard data block size of 2048 bytes (2 KB). The Microsoft implementation of CDFS includes a dynamic, protected-mode cache pool for caching CD-ROM data to improve read performance. This allows CDFS to read ahead to ensure that playback of multimedia content from CDs is smooth and seamless. On Windows 95 OEM Service Release 2 (OSR2), Windows 98, Windows Me, Windows NT, Windows 2000, Windows XP, and Windows .NET Server platforms, CDFS includes a number of enhancements over the original version of CDFS for Windows 95, such as

- CD-XA support for optimized reading of Moving Picture Experts Group (MPEG) video CDs having larger block sizes of 2352 bytes.
- Auto-Run, which allows applications on CDs to start immediately when the CD is inserted into the drive. To do this, the operating system reads the Autorun.inf file that is stored in the root of the directory structure on the CD.

C

CDFS does have several limitations compared to disk file systems such as FAT and NTFS, namely:

- Names for files and directories can be no longer than 32 characters
- Directories can be nested only eight levels deep

CDFS is now considered a legacy format and is being replaced by the industry-standard Universal Disk Format (UDF), the new standard for read-only disk media.

Notes

Using Services for Macintosh, you can create an Apple Macintosh-accessible volume on a CDFS volume by following the same steps you would use to make an NTFS volume accessible to Macintosh clients. Of course, the CDFS volume has one difference: it is read-only.

cell (ATM)

A 53-byte packet of data, the standard packet size used by Asynchronous Transfer Mode (ATM) communication technologies.

Overview

Cells are to ATM technologies what frames are to Ethernet networking. In other words, they form the smallest element of data for transmission over the network.

Cell in ATM. Details of an ATM cell.

ATM cells are standardized at a fixed-length size of 53 bytes to enable faster switching than is possible on networks using variable-packet sizes (such as Ethernet). It is much easier to design a device to quickly switch a fixed-length packet than to design a device to switch a variable-length packet. (Switching a fixed-length packet is easier because the device knows in advance the packet's exact length and can anticipate the exact moment at which the last portion of the packet will be received. With variable-length packets, the device must examine each packet for length information.) Using fixed-length cells also makes it possible to control and allocate ATM bandwidth more effectively, making support for different quality of service (QoS) levels for ATM possible.

The functions of information stored in the 5-byte header of an ATM cell include the following:

- Providing information about the physical layer transmission method being used
- Providing flow control to enable a steady flow of cell traffic and to reduce cell jitter
- Specifying virtual path or channel identification numbers so that multiplexed cells belonging to the same ATM connection can be distinguished from cells belonging to other ATM connections and cells can be switched to their intended destination
- Specifying the nature of the payload contained in the cell—that is, whether it contains actual user data or ATM cell-management information
- Specifying the priority of the cell to determine whether the cell can be dropped in congested traffic conditions
- Providing error checking by means of an 8-bit field containing cyclical redundancy check (CRC) information for the header itself

Two kinds of header formats are used in ATM cells:

- **User-Network Interface (UNI) format:** Used for communication between end nodes and an ATM network

- **Network-Node Interface (NNI) format:** Used within the ATM network itself after the cell has been multiplexed for transmission over its virtual path

Notes

Why a 48-byte data payload for ATM cells? This is the result of a trade-off between larger 64-byte payloads that contain more data but take longer to package and unpackage—and are therefore not suitable for real-time transmissions such as voice or multimedia—and shorter 32-byte payloads that provide better real-time transmission but are inefficient for larger amounts of data. By compromising at a 48-byte payload size, ATM has good transmission capabilities for both voice and data communication, providing efficient packet transfer with low latency.

cell (cellular communications)

In wireless communication technologies, the geographical region that is covered by a transmission facility.

Overview

The term **cell** is most often used in reference to cellular phone technology, but it can also be used in reference to the coverage areas for transmission of cordless telephones, satellite transmissions, wireless local area networks (LANs), packet radio, and paging technologies.

Cells range in size from a few dozen feet to thousands of miles in diameter, depending on the technology being used, the power of the transmission station, and the terrain topography. The following table summarizes typical cell size ranges for different wireless communication technologies. These figures are only approximate because wireless technologies are constantly evolving.

Satellite-based systems have by far the largest cell sizes and are rapidly increasing in popularity. Cellular phone technologies in rural areas typically use cells with a radius of 6 to 30 miles (10 to 50 kilometers), while cells in urban areas range in size from 0.6 to 6 miles (1 to 10 kilometers). For highly dense urban areas, cell sizes as

small as 330 feet (100 meters) can be used, especially in high-tier Personal Communications Devices (PCD) cellular technologies.

Cell Radius Measures by Technology

Wireless Technology	Cell Radius
Wireless LANs	10 to 100 meters
Cellular telephone	0.1 to 50 kilometers
PCD	0.1 to 1 kilometer
Satellite-based	1000 kilometers or more

Notes

When a mobile caller using a cell phone passes from one cell to another, the cellular phone system transfers the call to the system servicing the adjacent cell, a process called roaming.

Cellular Digital Packet Data (CDPD)

A type of packet-switched data transmission network operating as an overlay for a cellular communications system.

Overview

Cellular Digital Packet Data (CDPD) is a specification for overlaying digital data transmissions on the existing circuit-switched Advanced Mobile Phone Service (AMPS) analog cellular phone service. CDPD was developed by IBM together with a consortium of Regional Bell Operating Companies and other organizations to leverage the existing installed base of AMPS cellular equipment in the United States to provide low-cost, packet-switched data services. CDPD was first offered in 1994 by Bell Atlantic Mobile.

Uses

CDPD is typically used to provide wireless access to public packet-switched networks such as the Internet so that mobile users can access their e-mail and other services. Multiple users can share the same channel; the user's modem determines which packets are destined for the user's machine. CDPD also supports IP multi-

C

casting and is an open standard based on the Open Systems Interconnection (OSI) reference model for networking.

Architecture

CDPD makes use of idle times between calls in cellular phone network channels for interleaving packets of digital data. In other words, CDPD makes use of the “bursty” nature of typical voice transmission on the AMPS cellular system. Voice communication has gaps or pauses where packet data can be inserted and transmitted without interfering with the communication taking place between customers.

CDPD uses the Reed-Solomon forward-error-correcting code to encode each block or burst of data sent, and includes built-in RC4 encryption to ensure security and privacy of the transmitted data. CDPD is also based on the industry standard Internet Protocol (IP), allowing data to be transmitted to and from the Internet.

Although CDPD supports data transmission rates of 19.2 kilobits per second (Kbps) and higher, actual data throughput is usually around 9.6 Kbps. This is because of the large overhead added by CDPD to each data block transmitted. This overhead is designed to ensure that communications are reliable and to maintain synchronization between the modems at each end of the transmission. In addition, a color code is added to every data block to detect interference resulting from transmissions on the same channel from neighboring cell sites.

Implementation

A typical implementation of CDPD consists of three components:

- **Mobile-End System (M-ES):** A user device such as a laptop equipped with a cellular modem. This system communicates in full-duplex mode with a Mobile Data Base Station (MDBS) using the Digital Sense Multiple Access protocol, which prevents

collisions of data streams from multiple Mobile-End Systems.

- **Mobile Data Base Station (MDBS):** A telco device for receiving and transmitting CDPD data.
- **Mobile Data Intermediate System (MDIS):** Provides the central control for a CDPD network.

Marketplace

In the United States, the main providers of CDPD services are AT&T Wireless and Verizon Wireless. CDPD is also supported by several carriers in Canada and by AirData in New Zealand. CDPD is not widely deployed as a cellular data transmission technology, and coverage in the United States is spotty even in urban areas.

cellular communications

A group of technologies that support roaming cell-based wireless communications.

Overview

Common to all forms of cellular communications is the concept of the cell. Instead of using one extremely powerful transmission to provide coverage for a geographical area (for example, a city, state, region, or country), the area is divided into a series of overlapping smaller areas called cells. Each cell has a relatively low-power base station that provides coverage for users within that cell, and when a user moves (roams) from one cell to another, the first base station seamlessly hands off servicing of the user to the second base station and the user experiences no interruption in communication.

Cellular communications. How a cellular phone system works.

Dividing the coverage area into many cells makes cellular communications systems more complicated than systems that use a single high-powered base station. Complex functions such as call setup and tear down, call authorization, call handoff, routing of call traffic, and call billing must operate seamlessly as users move between cells, and they require complex technology to implement. These functions are provided by connecting groups of base stations to a mobile switching center

(MSC), which coordinates the activities of the base stations and connects them to the Public Switched Telephone Network (PSTN) so wireless users can call wireline users and vice versa.

Communications channels also need to be allocated to cells in such a way that no two adjacent cells use the same set of channels. This is necessary to ensure that signals from one base station do not interfere with those from base stations in adjacent cells. Repeating patterns of cells are used to optimize coverage of an area while maintaining the maximum number of available channels per cell. For example, in a typical cellular system, if you travel in a straight line every third cell utilizes the same set of frequencies.

Cells can also vary considerably in size. Because each cell can only support a certain number of users, cells in dense urban areas are much smaller than those in sparsely inhabited rural areas, and when population increases cells may need to be split to continue to provide adequate coverage. All this makes cellular communications complicated to implement, which explains why the technology took so many years to be widely deployed after the it was first conceived. The main advantage of such systems, however, is that, because cells are relatively small, the mobile client (cell phone or other device) does not need to be very powerful, which saves considerably on the size and the cost of the phone and has helped propel the widespread use and popularity of these systems.

History

The concept of a cellular phone system originated in 1947 at AT&T Bell Laboratories. AT&T first proposed a commercial cellular system to the Federal Communications Commission (FCC) in the late 1960s, and the FCC allocated the necessary frequency spectrum in 1974. A demonstration system was tested in Chicago in 1978, but the first actual cellular system was deployed in Japan in 1979 by the Nippon Telephone and Telegraph Company. This was followed by Europe in 1981, and finally in 1983 AT&T began deploying Advanced Mobile Phone Service (AMPS), the first nationwide cellular system in the United States.

C

AMPS was a first-generation (1G) analog cellular phone system that used frequency modulation for voice transmission and frequency-shift keying (FSK) for transmission of signaling information. AMPS uses channels within the 800 megahertz (MHz) frequency band of the electromagnetic spectrum, and channel access is provided by using Frequency Division Multiple Access (FDMA) as the media access method. AMPS achieved widespread implementation across the United States in the 1980s and is still widely used.

Another wave of cellular communications systems was developed in the 1990s and is still widely deployed. These second-generation (2G) systems differ from AMPS in being digital rather than analog in nature, and they can support not just voice but also data transmission, typically at 9.6 to 19.2 kilobits per second (Kbps). Several competing digital cellular systems have evolved and have become widely deployed:

- **Time Division Multiple Access (TDMA):** The main TDMA system deployed in the United States is AT&T Wireless Services, a subsidiary of AT&T. This TDMA system operates in the same 800 MHz frequency band as AMPS and is sometimes referred to as either Digital AMPS (D-AMPS) or North American TDMA (NA-TDMA).
- **Code Division Multiple Access (CDMA):** CDMA was developed by QUALCOMM, and its cdmaOne system is the most popular digital cellular system in North America. Other CDMA carriers include Bell Mobility, Sprint Corporation, and Verizon Communications. CDMA is more complex than TDMA, but it is more efficient in its utilization of the frequency spectrum.
- **Global System for Mobile Communications (GSM):** This system is based on TDMA and is the most popular digital cellular phone technology in Europe and much of Asia. GSM can operate in the 900, 1800, or 1900 MHz frequency bands. There are only a few GSM carriers in the United States, and they cover only a small portion of the market. An example is VoiceStream Wireless Corporation.
- **Personal Communications Services (PCS):** These systems can be TDMA-based or CDMA-based and operate in the higher 1900 MHz frequency band using smaller cell sizes than 800 MHz cellular systems. Sprint PCS, for example, is based on CDMA technology.

Issues

A major concern that has been receiving media attention lately is the safety of using cellular phones. While most agree that using a cellular phone while driving can increase the chances of an accident (and some civic and municipal governing bodies have passed laws regulating use of cellular phones while driving), scientists continue to debate whether other health hazards might be associated with the long-term use of cell phones. A particular concern is the possible link between cell phone use and brain cancer, particularly among children whose brains are still forming. Cell phones transmit microwave energy through their antennas, and microwaves have a known heating effect (think of a microwave oven, for example). When a cell phone is held next to the ear, some of the microwave energy penetrates into the brain, and while the FCC has mandated emission standards for cellular phones to keep these emissions below dangerous levels, some researchers believe that long-term exposure to even low-level microwave radiation may be harmful to the brain and other organs, particularly in children. On the other hand, many researchers believe that there is no conclusive link between brain cancer and cell-phone use, and in general such associations between cancer and environment factors are difficult to prove (consider how long it took to resolve the controversy over whether cigarettes caused lung cancer). The American Medical Association and other bodies continue to call for further study of these issues, but it will likely take years for studies to produce any significant results. Some governing bodies are already taking steps, however, such as the United Kingdom, which has mandated that mobile telephone handsets must now come with leaflets warning of potential health risks to children who use these devices over a prolonged period.

Impact

Cellular communications have revolutionized business and personal communications worldwide. About one-third of Americans now own cell phones, and this is growing at an annual rate of 25 percent. Use of cell phones in Europe and Asia is even higher on a percentage basis, and some analysts predict that by 2005 there will be more than 1.25 billion cell phones and other cellular communications devices used around the world.

Cell phones have helped catalyze the e-business revolution by providing employees with 24x7 connectivity with the office—something desirable from a management point of view but debatable in terms of the quality of life for workers. Using data-enabled cell phones and wireless Personal Digital Assistants (PDAs), workers can perform tasks such as sending and receiving e-mail, checking inventory and ordering products, reboot servers, and perform other essential tasks to keep an e-business operating. Nonbusiness uses of data-enabled cell phones including browsing the Web, checking weather reports, downloading news headlines, confirming airline reservations, checking stock quotations, and many other uses. Although many of these uses are exciting, most data operations are still tedious over slow 2G cellular systems, and the real promise of cellular Internet access will not be realized until 3G comes into full operation in the latter part of this decade.

Prospects

The current 2G cellular systems will be replaced over the next few years by broadband cellular systems that support much higher rates of data transmission than can now be achieved. Proposed 3G systems will support data transmission as fast as 2 megabits per second (Mbps) and include

- **Wideband CDMA (W-CDMA):** This system has the support of the International Telecommunication Union (ITU) as the upgrade for TDMA-based systems such as GSM, offers data rates of up to 2 Mbps, and is expected to become widely deployed in Europe and Asia.
- **CDMA2000:** This system has been proposed by QUALCOMM as the upgrade for CDMA systems,

has the support of the ITU as an alternative to W-CDMA, offers data rates of up to 2 Mbps, and is expected to become widely deployed in North America.

- **Enhanced Data rates for Global Evolution (EDGE):** This system is a proposed upgrade by AT&T for its North American TDMA system but offers data rates of only 384 Kbps.

Because 3G technologies are not expected to be deployed until 2003 (or more likely 2005), some carriers are implementing interim 2.5G systems to provide increased data rates over 2G until 3G becomes a reality. Some 2.5G systems starting to be deployed include

- **CDMA2000 1X:** This system developed by QUALCOMM supports data transmission at 307 Kbps, and is an interim step toward the 3G version CDMA2000 (sometimes called CDMA2000 2X).
- **General Packet Radio Service (GPRS):** This system upgrades AT&T's existing TDMA system to support data rates of 115 Kbps and is an interim step toward EDGE.

central office (CO)

A telco switching facility.

Overview

The central office (CO) provides access to the Plain Old Telephone Service (POTS), leased lines, and other services that a telco offers its customers in a given geographical area (usually a dozen square miles or so).

C

The CO contains the Class 5 switching equipment that connects telephone subscribers to both local and long-distance phone services. A telco typically has one CO servicing several dozen square miles in urban areas, so in large cities there may be many COs for each telco.

A typical CO may look like a fortress built to withstand an earthquake or any other natural disaster. Building standards for COs are high because of the importance of the communications infrastructure to a nation's economic health and safety. Banks of batteries and diesel generators provide backup power in case of blackouts so that phone communication will not be disrupted.

Multitudes of twisted-pair copper telephone lines from customer premises usually enter the building through the underground cable vault. These twisted-pair lines are grouped into bundles of thousands of lines, forming large cables 3 to 4 inches (7.5 to 10 centimeters) in diameter. The cables have grounding mesh to provide a drain for unwanted electrical surges and tough polyvinyl chloride (PVC) insulating jackets that are pressurized to prevent water from seeping in at cable junctions. Steel racks organize these cables as they enter the cable vault.

From the vault, the cables snake their way to the main cross-connect grid. It is in these steel-frame grids that all the individual twisted-pairs fan out and connect through feeders to the main switching equipment. The importance of the feeders is that they allow any incoming twisted-pair line to connect to virtually any switching bank. This makes it possible for customers to move to a different part of the city and maintain their old telephone number at their new location. It also allows for redundancy: if a switch fails, a CO technician can rewire the feeder blocks quickly and easily. The main switches are then used to route calls to other local subscribers or to a long-distance telecommunications carrier such as AT&T or MCI WorldCom. In the United States, these Class 5 telephone switches are usually Basic-5ESS switches, also called AT&T basic rate switches.

Subscribers are connected to their local CO through a segment of wiring called the local loop. This wiring is

typically copper, but telcos lay fiber to the building for customers requiring high-speed services not supported by copper lines.

Finally, a telco may have dozens of COs in a dense urban area, all interconnected using cross-links and redundant switches. Each CO services subscribers within a specific geographical area and manages voice and data traffic in that area. When a call is made from a customer over the local loop to the CO, the call is either switched to another circuit within the same exchange (for local calls) or switched to a trunk line joining the CO to a CO belonging to a different company, typically a long-haul carrier such as Sprint or AT&T. For business customers needing multiple telephone lines at their location, the carrier typically deploys a private branch exchange (PBX) at the customer premises.

Notes

Not all of a telco's switching and telecommunications equipment is located at a central office. There are recent trends where telcos have pushed out their ATM switching gear to within 500 feet (150 meters) of residential neighborhoods in pursuit of better-quality Digital Subscriber Line (DSL) connections. These remote stations shorten the copper DSL connections between customer premises and the provider's switching gear, and the remote Asynchronous Transfer Mode (ATM) concentrators are then connected to the COs using fiber.

In countries and regions other than the United States, a CO is often referred to as a public exchange.

Centrex

An acronym for **C**entral Office **E**xchange Service, a business telephone service provided by telcos.

Overview

By using a Centrex instead of a Private Branch Exchange (PBX), a business can eliminate the necessity of having its own dedicated switching facilities at its customer premises. Centrex also eliminates the need for customers to upgrade to expensive new telephones because existing telephone lines and touch tone phones

can be used with it. This frees the customer from the need to invest in the cost and management of customer premises equipment (CPE).

Centrex services partition the switching capabilities of the telco's central office (CO) equipment and allow a portion of these capabilities to be dedicated to a particular customer. In essence, the business customer is leasing dedicated switching facilities at the CO to enable a large number of employee telephones to be routed through a few telephone lines. All routing of calls to individual employee telephones takes place using the Centrex. Configuration changes can be performed at the CO instead of requiring technicians to visit the customer premises. This can save the cost of installing a local PBX at the customer premises.

Centrex can handle advanced communication features such as internal call handling, inbound and outbound call handling, and multiparty calling. Each individual connected can have customized calling features just as they can with a PBX. Maintenance is entirely the responsibility of the telco central office, which provides around-the-clock support.

Notes

Some carriers such as Pacific Bell Telephone Company also offer Integrated Services Digital Network (ISDN) as a Centrex service in addition to standard business ISDN lines.

certificate

Also called digital certificate, a technology for verifying the identity of the user or service you are communicating with.

See: digital certificate

certificate authority (CA)

Any entity (individual, department, company, or organization) that issues digital certificates to verify the identity of users, applications, or organizations.

Overview

Before issuing a digital certificate to someone, the certificate authority (CA) must verify the user's identity according to a strictly established policy, which can involve face-to-face communication, examination of a driver's license with photograph, or another method of establishing a user's identity. When the user's identity has been verified, the certificate is issued to the user. This certificate can then be presented by the user as a "digital driver's license" to identify himself or herself during network transactions.

CAs can be trusted third parties such as the private companies VeriSign, CyberTrust, and Nortel Networks; or they can be established within your own organization using Microsoft Certificate Server. CAs can be stand-alone authorities with their own self-signed certificates (that is, they validate their own identity as a root CA), or they can be part of a hierarchy in which each CA is certified by the trusted CA above it (up to a root CA, which must always be self-certified).

For digital certificates to work as an identification scheme, both client and server programs must trust the CA. In other words, when a client program presents a certificate to a server program, the server program must be able to validate that the certificate was issued by a valid and trusted CA. Certificate authorities also maintain a certificate revocation list (CRL) of revoked certificates. Certificates issued by CAs expire after a specified period of time.

CAs are necessary for the functioning of a public key infrastructure (PKI), which is essential to the widespread acceptance and success of any public key cryptography system. Microsoft Windows 2000 and Windows .NET Server can use standard X.509 digital certificates to authenticate connections across unsecured networks such as the Internet and to provide single sign-on using smart card authentication systems.

C

certificate mapping

A feature of Microsoft Internet Information Server (IIS) version 4 and Internet Information Services (IIS) version 5 (for Windows 2000) and later that allows mapping between user accounts and digital certificates.

Overview

Certificate mapping is useful when an organization issues client certificates to users. Client certificates are digital certificates that verify the identity of client software (Web browsers) belonging to users. Client certificates are often used in situations in which mobile clients using laptops require secure access to a corporate intranet site.

Before users can be granted remote access to the corporate intranet, they must be authenticated by the Web server they are connecting to. IIS supports four kinds of Web authentication mechanisms:

- **Anonymous access:** Allows anonymous users access to Web sites—such as public sites on the Internet.
- **Basic authentication:** Passes a user's credentials over the network as clear text. Although this mechanism is not very secure, it has the advantage of being able to work through a firewall or a proxy server.
- **Microsoft Windows NT Challenge/Response Authentication** (called Integrated Windows Authentication in Windows 2000): A secure authentication method that does not actually pass the user's credentials over the network but uses a cryptographic exchange instead. The only Web browser that supports this authentication method is Microsoft Internet Explorer. This method cannot work through a firewall or a proxy server.
- **Certificate mapping:** Uses the Secure Sockets Layer (SSL) protocol to authenticate users by examining the contents of their client certificate in order to log them on to the network without requiring them to enter their credentials.

Client certificates provide verification of identity, but certificate mapping associates a user's account with the user's client certificate and permits the user to log on to the network. The user typically utilizes a Web browser

with SSL protocol to connect to a secure company Web site. The company Web server checks the Web browser's client certificate. If the certificate is valid, the user is automatically logged on using his or her user account without ever having to enter credentials and can access whatever intranet resources for which the account has permissions.

IIS allows two kinds of client certificate mappings:

- One-to-one mappings between user accounts and client certificates on the user's browser. This type of mapping is typically used to allow users secure access to corporate intranet resources—for example, to view or modify their employee information.
- Many-to-one mappings can map several client certificates to a single user account. Many-to-one mappings have the advantage of permitting administrators to allow multiple certificates to be used to grant users access to the corporate intranet utilizing a single Windows account. For example, you can set a rule that maps all certificates issued by the CA of an agency that provides your company with temps to a single Windows account.

Notes

Certificate mapping is also supported by Active Directory directory service in Microsoft Windows 2000, Windows XP, and Windows .NET Server operating systems. You can use the Active Directory Users and Computers administrative tool for this purpose.

certificate request

A file containing an entity's identification information and public key that is submitted to a certificate authority (CA) in order to obtain a digital certificate.

Overview

A certificate request is a text file encoded using Base64 encoding. This text file is generated by an application in response to the entity's request for a key pair and digital certificate. The entity here refers to the individual, system, company, or organization requesting the certificate. The certificate request is then submitted to a CA to obtain a digital certificate for the entity.

The Key Manager utility in Internet Services Manager (the utility used to manage Microsoft Internet Information Services) can be used to generate a key pair and a standard public key cryptography standards (PKCS) #10 format certificate request file. The certificate request file is a simple text file that can be viewed with Microsoft Notepad. If this file is submitted to a public certificate authority, such as VeriSign, or to the company's own certificate authority, such as Microsoft Certificate Server, a standard X.509 format digital certificate will be granted in return.

certificate revocation list (CRL)

A list, maintained by a certificate authority (CA), of digital certificates that have been issued and later revoked.

Overview

A certificate revocation list (CRL) is similar to lists of revoked credit card numbers that credit card companies used to give to vendors. The certificate authority makes the CRL publicly available so that users can determine the validity of any digital certificate presented to them.

Creating and maintaining a CRL is an essential ingredient in running a public key infrastructure (PKI) to support public key cryptography systems. Microsoft Certificate Server includes a Web-based utility called the Certificate Administration Log Utility that can be used to revoke certificates and maintain a CRL.

Certified Technical Education Center (CTEC)

An education-delivery company, such as a school or training center, that is qualified by Microsoft Corporation for the delivery of Microsoft Official Curriculum (MOC) courseware.

Overview

Certified Technical Education Centers (CTECs) are one of Microsoft's main channels for training on Microsoft products and technologies. CTECs can deliver training in a variety of forms, including instructor-led, self-paced, customized, and online training. CTECs are one of the ways that Microsoft contributes to solutions addressing the shortage of skilled IT professionals worldwide.

Network professionals who want to become familiar with Microsoft operating systems, applications, and development platforms can take MOC courses offered by CTECs at various locations around the world. Microsoft CTECs are also a source for the best in self-paced training materials on Microsoft products and services.

For More Information

Visit the Microsoft CTEC site at www.microsoft.com/ctec.

Challenge Handshake Authentication Protocol (CHAP)

A standard form of challenge/response authentication protocol.

Overview

Challenge Handshake Authentication Protocol (CHAP) is a standard authentication protocol defined in RFC 1994. CHAP is one of several authentication schemes used by the Point-to-Point Protocol (PPP), a serial transmission protocol for wide area network (WAN) connections. Other authentication schemes supported by PPP include Password Authentication Protocol (PAP), Shiva Password Authentication Protocol (SPAP), and

C

Microsoft Challenge Handshake Authentication Protocol (MS-CHAP). PAP is a widely implemented authentication protocol, but CHAP is more secure than PAP because CHAP encrypts the transmitted password and PAP does not. SPAP and MS-CHAP are vendor-specific implementations.

CHAP is an encrypted authentication scheme in which the unencrypted password is not transmitted over the network. A typical CHAP session during the PPP authentication process works something like this:

- The client connects to a network access server (NAS) and requests authentication.
- The server challenges the client by sending a session ID and an arbitrary string.
- The client uses the MD5 one-way hashing algorithm and sends the server the username, along with an encrypted form of the server's challenge, session ID, and client password.
- A session is established between the client and the server.

To guard against replay attacks, the challenge string is chosen arbitrarily for each authentication attempt. To protect against remote client impersonation, CHAP sends repeated, random interval challenges to the client to maintain the session.

Notes

CHAP is supported by the Routing and Remote Access (RRAS) service of Windows 2000 and Windows .NET Server as a way to allow non-Microsoft clients to dial in and receive authentication for a Remote Access Server (RAS) session, and to allow Microsoft RAS clients to connect to any industry-standard PPP server.

With Cisco routers, CHAP repeatedly challenges the connecting host every two minutes after the connection is established. This helps to prevent session hijacking by hackers on the network.

challenge/response

A mechanism for securely authenticating users over a network.

Overview

Challenge/response provides a way of employing user credentials to negotiate a connection over a network without actually passing these credentials over the network. Challenge/response forms the basis of the Integrated Windows authentication method supported by Internet Information Services (IIS) on Microsoft Windows 2000, Windows XP, and Windows .NET Server (Integrated Windows authentication was previously called Windows NT Challenge/Response authentication in Internet Information Server [IIS] on Windows NT).

Implementation

The basic steps of challenge/response are straightforward and independent of the actual platform they are implemented on. Here are the steps in a typical challenge/response authentication session:

- The client contacts the server to access a resource on the server.
- The server requests the client to authenticate itself and sends the “challenge,” a randomly generated string, to the client.
- The client hashes the challenge string together with the client's password using a predetermined hashing algorithm. The result of this hash is called the “response.”
- The client sends the response to the server, together with the client's name.
- The server meanwhile has performed the identical hashing operation as the client has, using the client's credentials, which are securely stored ahead of time in the server's security database.
- When the server receives the client's hash, it compares this with its own hash. If the hashes are identical, the client's identity is authenticated and the client is allowed to access the desired resource.

Change and Configuration Management

A set of features in Microsoft Windows 2000, Windows XP, and Windows .NET Server for managing user settings and installing applications.

Overview

Change and Configuration Management is included in Windows 2000, Windows XP, and Windows .NET Server to provide support for tasks such as

- Installing initial operating systems on new computers
- Managing deployment of software on computers
- Managing user desktop configuration settings and user personal folders

Change and Configuration Management is an umbrella term for two underlying Microsoft technologies that make these things possible. These two technologies are

- **Intellimirror:** Enables management of user preferences, user documents, and software installation and maintenance.
- **Remote Operating System (OS) Installation:** Uses Remote Installation Services (RIS) to install Windows 2000, Windows XP, and Windows .NET Server on remote machines.

channel (Active Channel)

The delivery method in Active Channel, a technology for Microsoft Internet Explorer that allows Web content to be “webcast” to users.

Overview

Channels deliver content to users’ Web browsers. The content is displayed as ordinary Web pages and can be viewed off line. Channels are delivered to users by way of Microsoft Corporation’s Channel Definition Format (CDF) technology. Channels can contain Hypertext Markup Language (HTML); Microsoft ActiveX controls; Microsoft Visual Basic, Scripting Edition (VBScript); Java applets; and other dynamic Web

elements. The channels that a user has subscribed to are listed as part of his or her channel bar.

channel bank

A telecommunications device that consolidates multiple Digital Signal Zero (DS0) channels into a larger single digital transmission.

Overview

Channel banks usually combine 24 different voice and data 64 kilobits per second (Kbps) DS0 channels into a single 1.544 megabits per second (Mbps) DS1 channel, though some channel banks are capable of combining up to 96 DS0 channels into a 6.312 Mbps DS2 channel. The channel bank combines the individual DS0 signals using a technique called multiplexing, which allows multiple signals to be combined for transmission over a single line. The resulting multiplexed digital signal can then be sent over a T1 line to the telco.

A channel bank interfaces with the wires of the local loop connection that carry the phone signals from the customer premises to the telco’s central office (CO). In a typical business scenario, the channel bank would be connected to the front end of an analog Private Branch Exchange (PBX) to support multiple telephones within the company. The channel bank also includes circuits for converting the analog voice signals into digital data signals, usually using pulse code modulation (PCM). The resulting modulated digital signal conforms to the standard 64-Kbps DS0 format. The digital signals can then be routed through the digital switching backbone of the Public Switched Telephone Network (PSTN) as necessary.

Channel banks are typically located at the telco’s CO and support the digital switching functions of the PSTN. However, channel bank equipment can also be installed at customer premises for larger enterprises.

Notes

Channel banks are becoming obsolete as older analog PBXs are being replaced by digital PBXs. When a digital PBX is used, the PBX can be connected directly to

the T1 line using a Channel Service Unit (CSU), making a channel bank unnecessary.

channel bar

A component of Microsoft Internet Explorer version 4 and later that displays the available user-subscribed Active Channels.

Overview

Active Channels provide a way of webcasting information to subscribers using Microsoft Corporation's Channel Definition Format (CDF) technology. When Internet Explorer is first installed on a user's machine, a selection of preloaded channels is stored in the channel bar according to the country or region preference the user specified during installation. These channels are stored by default in C:\Windows\Favorites\Channels on a computer running Microsoft Windows 95 or Windows 98 and in C:\Winnt\Profiles\<user>\Favorites\Channels on a computer running Windows NT, Windows 2000, Windows XP, or Windows .NET Server. When a user subscribes to a channel, a small red gleam appears next to the icon representing the channel. This gleam indicates that new content has been downloaded and is available for browsing.

Notes

Administrators who plan to deliver and install Internet Explorer on users' machines can use the Internet Explorer Administration Kit (IEAK) to customize the users' set of startup channels. Administrators can thus use the channel bar to deliver important information to users through the company's intranet site.

See Also: *Channel Definition Format (CDF)*

Channel Definition Format (CDF)

An open standard created by Microsoft Corporation for Microsoft Internet Explorer version 4 (and proposed as a standard to the World Wide Web Consortium [W3C]) that defines a "smart pull" technology for webcasting information to users' desktops.

Overview

Based on the Extensible Markup Language (XML), Channel Definition Format (CDF) lets administrators create Active Channels for delivery of content through the user's Web browser and Active Desktop elements and channel screen savers for delivery directly to the user's desktop. Channel content can be personalized, and delivery can be scheduled according to users' needs and preferences. Using CDF also reduces server load and allows delivery of just the needed content, instead of requiring users to download large quantities of unnecessary content.

Consider the delivery of Web content to the user's browser using Active Channels. A Web site can be made into an Active Channel through the addition of a CDF file, a simple text file formatted using XML. It forms a kind of table of contents of the logical subset of the Web site that comprises the Active Channel. A link is then created to the CDF file on the Web site. The user clicks the link to subscribe to the Active Channel and download the CDF file. The Active Channel then appears on the channel bar on the user's desktop. The content for the channel is downloaded to a cache on the user's system. Channel updates are accomplished by scheduled Web crawls, using either the publisher's predefined schedule or a user's customized one. Users can also receive updates to channels by e-mail.

Some of the advantages of using CDF for the distribution of Web information to users include

- **Simplicity:** Turning an existing Web site into a channel merely involves creating a CDF file with a text editor and creating a hyperlink to this file.
- **Structure:** CDF describes how to logically group information in a hierarchical structure, independent of the content format.
- **Personalization:** Standard Hypertext Transfer Protocol (HTTP) cookies can be used to deliver personalized information to users.
- **Administrator control:** The administrator can control how much of the site can be downloaded by users.

- **User control:** The user can use CDF to specify which portions of a site to download to his or her browser, instead of pulling a lot of content off the site and hoping that it contains the needed information.

Notes

CDF is not true webcasting in the sense of Internet Protocol (IP) multicasting because it is a “pull” technology. True webcasting is supported by Microsoft Windows Media Player for delivery of content using IP multicasting.

channel (Microsoft Windows Media Player)

In Microsoft Windows Media Player, a mechanism that supplies clients with information needed to receive and render Advanced Streaming Format (ASF) streams.

Overview

A Windows Media Player channel specifies the multicast address and port number the clients should listen to in order to receive the stream. The channel also specifies the data types and formats in the stream, enabling the client to correctly render the stream. Windows Media Player saves channel information as files with the extension .nsc. A Windows Media Player channel is analogous to a television channel or a radio frequency: if a Windows Media Player client is tuned to a channel at the right time, the client receives streaming information sent by the Windows Media Player server.

Windows Media Player channels also support additional features, such as

- **Roll over to unicast:** If clients cannot receive a multicast, you can configure the channel so that they automatically receive a unicast of the same program.
- **Stream distribution:** On corporate Transmission Control Protocol/Internet Protocol (TCP/IP) networks whose routers do not support multicasting, one Windows Media Player server can distribute a stream to other Windows Media Player servers that are each located on separate local area network (LAN) segments. These secondary servers can then multicast to clients on their own LAN segment.

Channel Service Unit (CSU)

A device that is used to connect a synchronous digital telecommunications line to a computer network.

Overview

Channel Service Units (CSUs) are used to link local area networks (LANs) into a wide area network (WAN) using telecommunications carrier services such as Digital Data Services (DDS), T-carrier services such as a T1 line, and frame relay links.

The function of a CSU is to terminate the carrier's digital line at the customer premises. It also provides signal amplification and allows the carrier to perform remote loopback testing to monitor and troubleshoot the integrity of the line. Some CSUs also support Simple Network Management Protocol (SNMP) features that allow the unit to be monitored by the service provider.

Channel Service Unit (CSU). Using a CSU in a WAN link.

CSUs are always used together with Data Service Units (DSUs), which convert signals from data terminal equipment (DTE) such as a router, switch, multiplexer (MUX), or dedicated server on the LAN to a signaling format suitable for transmission over the line.

C

Implementation

The service provider interface of the CSU terminates at the telco's digital line where it enters the customer premises. The other interface of the CSU then connects to a DSU, and then the DSU connects with data terminal equipment (DTE) on the LAN (a router, switch, or other LAN device). The DTE is typically an RS-232 or a V.35 serial transmission interface.

Typically, the telecommunications service provider will lease the CSU to the customer, having preconfigured it for the type of digital line to be supported. CSUs usually come in a dual Channel Service Unit/Data Service Unit (CSU/DSU) package that drops into the edge of the network to provide WAN link connectivity.

Dedicated stand-alone CSUs are typically used only for interfacing with installed customer premises telecommunications equipment that contains integrated DSUs. This installed equipment could be a channel bank, Private Branch Exchange (PBX), T1 multiplexer, or some other device. Some access routers have built-in CSU/DSUs as well.

Channel Service Unit/Data Service Unit (CSU/DSU)

A device that combines the functions of both a Channel Service Unit (CSU) and a Data Service Unit (DSU).

Overview

Channel Service Unit/Data Service Units (CSU/DSUs) are placed between the telephone company network and the customer network at the demarcation point and are the local interfaces between the data terminal equipment (DTE) at the customer premises and the telco's digital communications line (such as a T1 line).

CSU/DSUs package digital data into a format suitable for the particular digital transmission line they are servicing and buffer and rate-adapt digital signals going to and from the telephone company network. CSU/DSUs ensure that data frames are properly formed and timed for the telephone company network and provide a protective barrier to electrical disturbances that can harm customer premises equipment (CPE).

Channel Service Unit/Data Service Unit (CSU/DSU).

Using a CSU/DSU to connect two local area networks (LANs) over a wide area network (WAN) link

Implementation

CSU/DSUs essentially function as the digital counterpart to analog modems. They are typically external units that look similar to an external modem, but they can also come in sizes that can be mounted in a rack. Unlike analog modems, CSU/DSUs do not perform signal conversion because the signal at both ends is already digital.

Digital lines usually terminate at customer premises with four-wire connections having various connector types, including RJ-45, four-screw terminal blocks, and M-block connectors (used for V.35 interfaces). The four-wire connection is joined to the appropriate connector on the CSU/DSU. The CSU/DSU typically adjusts itself to the line speed of the digital data service (DDS) line using an autosensing feature. The customer's CSU/DSU then connects directly to the customer's router and from there connects to the customer's network.

At the other end of the DDS line at the central office (CO), the telco has a similar CSU that interfaces with a multiplexer to feed into the carrier's backbone network.

Notes

When purchasing CSU/DSUs, consider first the traffic requirements of your wide area network (WAN) link and make sure they support the full range of data rates for the DDS lines you plan to use (56 K, 64 K, or T1 speed).

child domain

A domain in a Microsoft Windows 2000 or Windows .NET Server domain tree whose Domain Name System (DNS) name is a subdomain of the parent domain.

Overview

As an example, if the name of the parent or company domain is microsoft.com, some typical names of child domains might include dev.microsoft.com, marketing.microsoft.com, and support.microsoft.com.

You can create new child domains using the Active Directory Installation Wizard. You must create a child domain in an existing domain tree, because creating a new tree automatically creates a new parent domain. A two-way transitive trust exists between a parent domain and its child domains.

CIM Object Manager (CIMOM)

Part of the Microsoft Windows Management Information (WMI) architecture.

Overview

CIM Object Manager (CIMOM) functions as a broker for object requests within the WMI architecture. CIMOM supplies the required interfaces between management applications (WMI consumers) and a managed physical or logical network object (WMI providers).

CIMOM abstracts management information from a variety of different providers, including the Win32 programming interfaces for Windows applications and the Simple Network Management Protocol (SNMP) for managed network devices. CIMOM then employs the WMI application programming interface (API) to present the gathered information in a consistent fashion to the network management application.

C

A network management application can register with CIMOM in order to receive notifications when specific network events occur, such as a full disk or a saturated network path. If such a condition arises, the WMI provider for the managed device or application sends a notification to CIMOM, which notifies the registered management application of the condition.

circuit

A path between two points over which an electrical signal can pass.

Overview

In telecommunications, a circuit is a path over which voice, data, or other analog or digital signals can pass. A physical circuit is a collection of wires or cables that are connected with switches or other devices; it can be thought of as a straight line between the two endpoints.

Unbalanced circuit

Balanced circuit

Circuit. Two basic types of circuits.

For an electrical signal to actually flow between two points in a circuit, the circuit must be closed—that is, there must be a return path for the current. Two basic types of circuits are used in serial transmission for telecommunications technologies:

- Balanced circuits, such as those based on the RS-422 interface, use a separate signal path and return path, with two separate wires.
- Unbalanced circuits, such as those based on the RS-232 interface, use a single signal path, adding ground to complete the circuit.

Balanced circuits typically support higher data transmission rates because they are less susceptible to noise caused by electromagnetic interference (EMI) than unbalanced circuits.

Notes

A typical serial interface such as RS-232 includes specifications for a number of different types of circuits, including data circuits, control circuits, timing circuits, secondary circuits, and ground connections.

circuit layer proxy

Any service or server that provides proxy services using a specially installed component on the client computer

to form a circuit between the proxy server and the client computer.

Overview

Microsoft Proxy Server is a product that combines firewall and proxy server functions and has two services for providing circuit-level proxy functions:

- **Winsock Proxy Service:** This enables Microsoft Windows Sockets clients such as Microsoft Windows Media Player, RealAudio, and Internet Relay Chat (IRC) to function as if they are directly connected to the Internet. The Winsock Proxy Service provides Windows NT Challenge/Response Authentication with clients, regardless of whether the clients support it, and supports Windows Sockets version 1.1-compatible applications on computers running Windows. The Winsock Proxy Service can control access by port number, protocol, and user or group. Ports can be enabled or disabled for specific users or groups, and the list of users that can initiate outbound connections on a given port can differ from the list of users that can listen for inbound connections on that port.
- **SOCKS Proxy Service:** This includes support for the SOCKS 4.3a protocol. The SOCKS Proxy Service provides support for Macintosh-based and UNIX-based client computers, while the Winsock Proxy Service supports only Windows-based computers. SOCKS uses Transmission Control Protocol (TCP) and can be used to control access to the Telnet, File Transfer Protocol (FTP), Gopher, and Hypertext Transfer Protocol (HTTP) protocols. The SOCKS Proxy Service does not support RealAudio, streaming video, or Windows Media Player clients.

Notes

Circuit layer proxies support a wider variety of protocols than application layer proxies.

See Also: application layer proxy

circuit-level gateway

A type of firewall that provides session-level control over network traffic.

Overview

Similar in operation to packet filtering routers, circuit-level gateways operate at a higher layer of the Open Systems Interconnection (OSI) reference model protocol stack. Circuit-level gateways are host-based and reside on individual clients and servers inside the network, rather than on a dedicated machine as they do with other types of firewalls. Circuit-level gateways examine incoming Internet Protocol (IP) packets at the session level—Transmission Control Protocol (TCP) or User Datagram Protocol (UDP)—and act as relays by handing off incoming packets to other hosts. Circuit-level gateways are rarely used as a stand-alone firewall solution; instead, they are typically used in combination with application layer proxy services and packet filtering features in dedicated firewall applications.

Microsoft Proxy Server combines the features of packet filtering, circuit-level gateways, and application layer proxy to provide a full firewall solution for protecting your corporate network. Proxy Server supports both the SOCKS protocol, which provides nontransparent circuit-level gateway security, and the Winsock Proxy, which provides transparent circuit-level gateway security.

circuit-switched services

A term describing any telecommunications service that provides switched connections between a telco and their customers.

Overview

Circuit switching is the oldest form of digital communications used by telecommunications carriers. Circuit-switched telecommunications services can be provided to businesses by both local telcos and long-distance carriers. The Public Switched Telephone Network

C

(PSTN) is the classic example of a circuit-switched service (even its earlier analog form as the Plain Old Telephone System [POTS], it was also circuit-switched in operation). Another common example, often used for wide area network (WAN) connectivity between companies and remote branch offices, is Integrated Services Digital Network (ISDN).

Circuit-switched services. How typical circuit-switched services work.

Circuit-switched services are generally more suitable than packet-switched services for real-time transport of delay-sensitive traffic such as voice and video. This is because, after the circuit has been set up for a given connection, traffic is routed with minimal delay to its destination. Circuit-switched services offer guaranteed delivery and differentiated services that are only beginning to be offered by packet-switched services such as Ethernet that carry best-effort Internet Protocol (IP) traffic.

Uses

In the enterprise, circuit-switched services are often used as backup lines for more expensive leased lines. For example, if your more expensive T1 line fails, you can switch to a dial-up ISDN line (if it comes from a different provider). When using circuit-switched services, it is a good idea to monitor their usage because when a certain usage level is reached, leased lines may become economically preferable. Leased lines such as T1 lines use dedicated switches that are set up in a permanent configuration for as long as the customer leases the services.

Implementation

With circuit-switched services, a new switched circuit must be established each time one local area network (LAN) attempts to connect to a remote LAN. Circuit-switched services are temporary circuits only, and when the connection is terminated the circuits are torn down. Different switches can be used for each connection established, depending on availability and traffic, so the quality of services can vary between connections.

Typically, your corporate LAN is connected to these services through bridges, routers, modems, terminal adapters, or other equipment, depending on the type of service being offered. At the other end of the connection is the telco central office (CO), which sets up switches on demand to connect you to your remote branch office LAN. When you disconnect the WAN link, the switches are freed up for other purposes.

Advantages and Disadvantages

One advantage of circuit-switched services is that they are generally less expensive than leased lines. This is because switches are not dedicated to your network as leased lines are, and can therefore be used for other purposes when you are not using them. The cost for circuit-switched services is usually based on usage.

Another advantage of circuit-switched services is that you are not restricted to a single destination as you are with leased lines; you can dial up any destination that supports services similar to yours.

A disadvantage with circuit-switched services is that they are usually dial-up in nature, and a dial-up connection takes time to be established. This connection time varies with the technology used. For example, analog modems might take 10 to 20 seconds to establish a connection, and an ISDN terminal adapter might take only 1 to 2 seconds. This latency interval tends to make circuit-switched lines unsuitable for dedicated services, such as those used for connecting company Web servers to the Internet.

Another disadvantage of circuit-switched services is that the quality can differ substantially between connections, because each circuit is a temporary connection that can exist along different paths, switches, and communication devices.

circular logging

A feature of Microsoft Exchange Server whereby transaction logs can be overwritten when full. Circular logging lowers disk space usage but reduces the chances of successfully recovering from a system crash.

Overview

Exchange Server databases, such as the directory database and information store, maintain special log files called transaction log files. These log files improve the performance and fault tolerance of the databases, and help track and maintain changes made to them. Transactions are immediately written both to the log files and to memory, and only afterward to the database files.

Transaction logs are normally kept on a different drive from the database files to ensure fault tolerance in case of a disaster that causes data loss, such as a crashed disk or a power failure.

When circular logging is enabled, only a few transaction log files are maintained, and these are overwritten when they become full. This prevents log files from continually building up, which saves disk space. However, circular logging has the disadvantage of allowing you to perform only full backups, rather than incremen-

tal or differential ones, because you can restore information only up to the last full backup.

Notes

Do not use circular logging if data recoverability is of high importance to your mail system, which is almost always the case with e-mail. Circular logging is enabled by default. You should always disable it and ensure that you have enough free disk space to hold the transaction files. The only reasons you might want to enable circular logging would be if you run low on disk space or if your server is being used for noncritical data only, such as a public news server.

class

More precisely called “object class,” a logical grouping of objects within Active Directory directory service in Microsoft Windows 2000 and Windows .NET Server.

Overview

Objects are organized within Active Directory by their classes. Examples of object classes can include users, groups, computers, domains, and organizational units (OUs). Each class of objects has its own defining properties or attributes, as laid out in the Active Directory schema. Grouping objects logically into classes makes it easier to find and access these resources on the network.

Active Directory comes with predefined object classes. You can create additional classes or modify existing ones using the Active Directory schema.

Class A

A type of Internet Protocol (IP) network where the first octet of IP addresses ranges between 0 and 126 inclusive.

Overview

Class A networks were originally intended for very large internetworks. Using the default class A subnet mask of 255.0.0.0, each class A network can support a maximum of 16,777,214 individual hosts with unique IP addresses—large enough for the largest of enterprise networks. However, there are no longer any Class A networks available since all 125 of them were assigned

C

in the 1980s to large corporate customers, organizations, and the military. None of these organizations actually has networks large enough to require the full 16 million host addresses provided by their Class A addresses, so classless interdomain routing (CIDR) was developed by the Internet Engineering Task Force (IETF) to allow unused Class A addresses to be reassigned to other users.

Notes

For a huge private network not directly connected to the Internet or hidden behind a firewall using Network Address Translation (NAT), the Internet Assigned Numbers Authority (IANA) recommends using Class A addresses whose first octet is 10. This provides millions of possible host addresses ranging from 10.0.0.1 to 10.255.255.254.

The Class A address 127.0.0.1 is reserved for loopback and represents the local host being used.

Class B

A type of Internet Protocol (IP) network where the first octet of IP addresses ranges between 128 and 191 inclusive.

Overview

Class B networks were originally intended for large internetworks. Using the default Class B subnet mask of 255.255.0.0, each Class B network can support up to 65,534 individual hosts with unique IP addresses—large enough for the largest of enterprise networks. There are 65,536 possible Class B networks that can be assigned, and in the early days of internetworking a number of these network IDs were assigned to large corporations and to the military by the Internet Assigned Numbers Authority (IANA). Today it is virtually impossible to obtain a class B network ID.

Notes

For a large private network not directly connected to the Internet or hidden behind a firewall using Network

Address Translation (NAT), IANA recommends using Class B addresses whose first two octets range from 172.16 to 172.31. This provides many thousands of host addresses ranging from 172.16.0.1 through 172.31.255.254 and up to 16 different subnets if required.

class-based queuing (CBQ)

An emerging technology for wide area network (WAN) traffic management.

Overview

Traditionally, WAN traffic for different classes of service (CoS) have been managed using router-based schemes that provide best-effort control of bandwidth allocation. For example, a router might be configured to allow no more than 20 percent of available bandwidth for streaming video. Such a bandwidth allocation is relative (percentage) rather than absolute (bps) in nature, which does not give much granularity for control of traffic, particularly mission-critical network traffic.

Class-based queuing (CBQ) is an emerging technology for WAN access routers that allows network managers to classify traffic types into a hierarchy of classes and then assign absolute bandwidth allocations to each type. For example, CBQ could first be used to divide traffic types according to different kinds of business applications and then to create a second level classifying traffic according to the department using the application. The customer relationship management (CRM) software used by the marketing department could then be assured a given minimum bandwidth.

Implementation

CBQ operates at Level 2 (the network layer) for IP traffic and works with any IP protocol including Transmission Control Protocol (TCP), User Datagram Protocol (UDP), or Internet Control Message Protocol (ICMP). To implement CBQ in a corporate WAN setting, a CBQ-capable access router would be inserted at the WAN edge of each corporate local area network (LAN) and configured with suitable classes to control

allocation of bandwidth for WAN traffic. CBQ classes are implemented on routers by using policies.

Class C

A type of Internet Protocol (IP) network where the first octet of IP addresses ranges between 192 and 223 inclusive.

Overview

Class C networks were originally intended for small internetworks. Using the default Class C subnet mask of 255.255.255.0, each Class C network can support up to 254 individual hosts with unique IP addresses. There are 16,777,216 possible Class C networks that can be assigned, and it is relatively easy to obtain a Class C network ID from your Internet Service Provider (ISP) should your company require it.

Notes

For a small private network not directly connected to the Internet or hidden behind a firewall using Net-

work Address Translation (NAT), the Internet Assigned Numbers Authority (IANA) recommends using Class C addresses whose first three octets range from 192.168.0 through 192.168.255. This provides thousands of host addresses ranging from 192.168.0.1 through 192.168.255.254 and up to 256 different subnets if required.

Class D

A type of Internet Protocol (IP) network where the first octet of IP addresses ranges between 224 and 239 inclusive.

Overview

Class D addresses are used exclusively for multicasting purposes. Most Class D addresses whose first octet is 224 are reserved for special purposes, as shown in the table. For multicasting within a private network not directly connected to the Internet or hidden behind a firewall using Network Address Translation (NAT), the Internet Assigned Numbers Authority (IANA) recommends using Class D addresses whose first octet is 239. For multicasting over the Internet you must first obtain a multicast address from IANA.

Examples of Some Reserved Class D Addresses with First Octet 224.

Address	Reserved for
224.0.0.1	Multicasting to all hosts on the local subnet
224.0.0.2	Multicasting to all routers on the local subnet
224.0.0.4	Multicasting to all Distance Vector Multicast Routing Protocol (DVMRP) routers
224.0.0.5	Multicasting to all Multicast Open Shortest Path First (MOSPF) routers
224.0.0.9	Multicasting to all Routing Internet Protocol version 2 (RIPv2) routers
224.0.0.10	Multicasting to all Interior Gateway Routing Protocol (IGRP) routers
224.0.18.255	Dow Jones multicasting service

C

Class E

A type of Internet Protocol (IP) network where the first octet of IP addresses ranges between 240 and 255 inclusive.

Overview

Class E addresses are reserved for research and experimental purposes, and are not used in ordinary computer networking. Class E addresses have a first octet that ranges from 240 to 255. The only Class E address commonly used is 255.255.255.255, which represents a local area network (LAN) broadcast.

classful domain

An Internet Protocol (IP) network that uses a default subnet mask.

Overview

A classful domain is an IP network that contains only the single default subnet. All hosts on the network are therefore in the same broadcast domain. For example, a network that is using a Class A address such as 10.0.0.0 and the default subnet mask 255.0.0.0 is a classful domain. The same would be true of a network using a Class B address such as 172.11.0.0 with subnet mask 255.255.0.0 and a network using a Class C address such as 192.16.33.0 with subnet mask 255.255.255.0—all three of these are examples of classful domains and are networks with only one subnet and therefore one broadcast domain.

Generally speaking, classful domains are not the way to go as they are very busy places with respect to traffic and may be susceptible to broadcast storms. Large networks are thus subnetted into a group of subnets forming what is called a classless domain.

classful routing protocol

A routing protocol for classful networks.

Overview

Classful routing protocols require that all Internet Protocol (IP) addresses on a network have the same subnet mask. For example, if a Class B network ID of 172.24.0.0 is subnetted into several subnets such as

172.24.1.0, 172.24.2.0, and 172.24.3.0, then classful routing requires that all these subnets have the same subnet mask. The reason for this limitation is that when routers using classful routing protocols exchange routing table updates with one another, the subnet mask is not included in the updates.

Examples of common classful routing protocols include Routing Information Protocol (RIP) versions 1 and 2, and Interior Gateway Routing Protocol (IGRP).

Classical IP (CIP)

A method for running Internet Protocol (IP) over Asynchronous Transfer Mode (ATM).

Overview

Classical IP (CIP) is an alternative to LAN Emulation (LANE) as a way of transporting IP packets over Asynchronous Transfer Mode (ATM) networks. CIP is based on RFC 1577 and supports only IP and no other network protocols (LANE can also be used to transport multiprotocol traffic such as IP and Internetwork Packet Exchange [IPX] over ATM). CIP has a number of benefits that make it an attractive solution in many situations:

- CIP is fast—speeds of 25 megabits per second (Mbps), 155 Mbps, 625Mbps, and 2.4 gigabits per second (Gbps) are supported, making it competitive with Fast Ethernet and Gigabit Ethernet (GbE) as a network transport.
- CIP is a circuit-switched technology that provides full bandwidth to each station on the network.
- CIP is simpler to implement, manage, and troubleshoot than LANE and utilizes fewer ATM resources (virtual circuits).
- CIP utilizes bandwidth effectively by eliminating broadcast traffic (as described later).

Implementation

CIP groups IP hosts together into groupings called logical IP subnets (LISs). Each LIS has an Address

Resolution Protocol (ARP) server to support IP broadcasts. Because broadcasts are essential to IP for the operation of the ARP, CIP implements a device called an ARP server to eliminate the need for these broadcasts. This is necessary because ATM in itself does not support broadcasts. When an IP host appears on a CIP network, it first registers itself with the ARP server so that IP communications can take place.

When an IP host needs to communicate with a target host on the network, it passes the IP address of the target host to the ARP server in the LIS, which returns the ATM address of the target host. To make this possible, the ARP server must be preconfigured with mappings of the IP and ATM addresses of each IP host in the LIS. When the host knows the target host's ATM address, a switched virtual circuit (SVC) can be established between the two hosts and IP packets can be transmitted to the target host.

An alternative implementation of CIP is called CIP over PVC (permanent virtual circuit). This is used primarily for wide area network (WAN) connections that are always on.

Classic desktop

A way of displaying the desktop and its contents that was first used in Microsoft Windows 95.

Overview

The Classic desktop presents users with a graphical user interface (GUI) that allows icons, shortcuts, files, and folders to be placed on it. These desktop items provide a simple way for users to launch and access frequently used programs and network resources. The Start menu provides another tool for launching programs and accessing resources. The taskbar displays the programs currently running and the Windows-to-network resources that are open.

The choice of GUI for users' client computers can make a big difference in employee productivity. The following are two factors involved in determining whether network administrators should maintain the Classic

desktop or upgrade to the newer Active Desktop included with Microsoft Internet Explorer beginning with version 4:

- The cost of introducing users to the new desktop paradigm
- The necessity for tight integration among the desktop, the corporate network, and the Internet

Classic desktop. The Classic desktop, first used in Windows 95.

classless domain

An Internet Protocol (IP) network that uses a variable-bit subnet mask.

Overview

A classful domain is an IP network that uses a default subnet mask such as 255.0.0.0 for Class A networks, 255.255.0.0 for Class B, or 255.255.255.0 for Class C. Classful domains thus have only one subnet and one broadcast domain. By contrast, a classless domain is an IP network that uses a variable-bit subnet mask (VBSM), also called a classless subnet mask, to divide the network into two or more subnets, each of which represents a different broadcast domain.

Classless domains are generally built using routers. Each subnet within a classless domain constitutes a unique broadcast domain and collision domain, which generally improves performance over using a single broadcast and collision domain. Switches operate at the

C

data-link layer and can partition a network into different collision domains, but they do not create different broadcast domains.

classless interdomain routing (CIDR)

Also called supernetting, an alternative way of classifying Internet Protocol (IP) addresses from the traditional Class A-E system.

Overview

Classless interdomain routing (CIDR) is a more efficient routing mechanism than the original method of segregating network IP addresses into classes named Class A, B, and C. The trouble with the old system is that it leaves too many unused IP addresses. For example, while Class A networks support large numbers of network nodes, there are not enough Class A networks to go around and none of the owners of these networks make anywhere near full use of the large number of IP addresses available to them. As a result, large numbers of Class A (and Class B) IP addresses go unused, and CIDR was developed as a way of reclaiming those IP addresses for allocation elsewhere. Similarly, while many Class C network IDs are available, many companies require more than the 254 IP addresses available on a Class C network, but not nearly as many as the 65,534 IP addresses available on any Class B network.

History

In the late 1980s, prescient architects of the Internet foresaw that the standard Class A-E method for assigning IP addresses would eventually fail and that the routing tables used by the core routers of the Internet's backbones would eventually grow unmanageably large. The class system provides for a huge number of IP addresses, but for only about 2 million different IP networks. As the number of networks attached to the Internet grew exponentially, a time was anticipated when there would be no more network numbers left to assign for new Class B and C networks (all Class A networks were assigned early on).

In the early 1990s the Internet Engineering Task Force (IETF) produced a group of Requests for Comments

(RFCs), namely RFCs 1517 to 1520, that brought a way out of the dilemma. These RFCs formed the basis of CIDR and provided a way of not only reducing the growing load on the Internet's core routing tables (another result of the Internet's rapid growth) but also of reusing unused IP addresses to make about 8 million additional IP networks of Class C size available for assignment to other companies and organizations.

Uses

CIDR is used primarily by routers and gateways on the backbone of the Internet for routing packets across the Internet. CIDR is not used much in private networks because most networks are hidden behind firewalls and can use any arbitrary block of IP addresses, such as the 10.x.y.z block allocated by Internet Network Information Center (InterNIC) for general, private use. Instead, CIDR comes into its own on the Internet backbone to facilitate routing and ensure the continued functioning of the Internet. However, CIDR is viewed only as a workaround to the issues of insufficient numbers of IP networks available for allocation and maintaining the routing tables of backbone routers at workable sizes. Most Internet architects see IPv6 as the real solution to these issues and expect the need to change over to this system of addressing in the next few years.

Implementation

CIDR replaces the old class method of allocating 8, 16, or 24 bits to the network ID, and instead allows any number of contiguous bits in the IP address to be allocated as the network ID. For example, if a company needs a few thousand IP addresses for its network, it can allocate 11 or 12 bits of the address for the network ID instead of 8 bits for a Class C (which would not work because you would need to use several Class C networks) or 16 bits for Class B (which is wasteful).

CIDR assigns a numerical prefix to each IP address. For example, a typical destination IP address using CIDR might be 177.67.5.44/13 (the last part being pronounced "slash thirteen"). The suffix /13 indicates that the first 13 bits of the IP address identify the network, while the remaining $32 - 13 = 19$ bits identify the host. In subnetting notation, the CIDR address 177.67.5.44/13 would be equivalent to the combination of IP address 177.67.5.44 and subnet mask 255.255.128.0 (see the

following table). As another example, in CIDR notation an old style class B network 132.16.0.0 with default subnet mask 255.255.0.0 would be represented simply as 132.16/16.

The prefix helps to identify the Internet destination gateway or group of gateways to which the packet will be forwarded. Prefixes vary in size, with longer prefixes indicating more specific destinations. Routers use the longest possible prefix in their routing tables when determining how to forward each packet. CIDR enables packets to be sent to groups of networks instead of to individual networks, which considerably simplifies the complex routing tables of the Internet's backbone routers. The table shows the different CIDR values and their subnet mask equivalents.

CIDR Values and Their Subnet Mask Equivalents

<i>Class</i>	<i>CIDR Value</i>	<i>Subnet Mask</i>
Class A	/8	255.0.0.0
	/9	255.128.0.0
	/10	255.192.0.0
	/11	255.224.0.0

	/25	255.255.255.128
	/26	255.255.255.192
	/27	255.255.255.224
	/28	255.255.255.240
	/29	255.255.255.248
	/30	255.255.255.252
	/31	255.255.255.254
	/32	255.255.255.255

Notes

There might seem to be an alternate solution for avoiding the waste of IP addresses from Class A and Class B networks. Consider, for example, a company with a network of 5,000 nodes. Assigning a single Class B network ID such as 166.33.0.0 to the network would provide 65,534 possible IP addresses for hosts, which is far too many—60,534 addresses would remain unused. A solution to this might seem to be assigning the company a contiguous set of 20 Class C network IDs. Because each Class C address provides 254 possible host addresses, 20 contiguous Class C network IDs, such as 198.15.1.0 through 198.15.20.0, would provide $20 \times 254 = 5080$ possible IP addresses, which is just right, plus a few to spare.

Using this technique does eliminate the wasting of IP addresses, but it creates a new problem: to handle routing between your corporate network and the Internet, you need to add 20 new entries to the routing tables on Internet routers, one entry for each network ID you are using. Following this method quickly overwhelms the routers that form the Internet's backbone because as their routing tables grow their performance slows down. CIDR was devised to address this very issue by decreasing the number of entries required in the Internet's routing tables. CIDR does this by supernetting the 20 Class C networks above into a single supernet, which needs only one entry in the routing tables.

classless routing protocol

A routing protocol for classless networks.

Overview

Classless routing protocols allow different portions of an Internet Protocol (IP) network to use different subnet masks for the same network ID. Then, when routers using classless routing protocols exchange routing table updates with one another, the subnet mask is included in each update. Thus, given a single IP network ID, variable length subnet masking (VLSM) may be used to create different subnets having different subnet masks. Classless routing protocols also help conserve network resources by using route summarization.

C

Examples of common classless routing protocols include Border Gateway Protocol (BGP), Enhanced Interior Gateway Routing Protocol (EIGRP), and Open Shortest Path First (OSPF).

cleartext

The process of sending data over a network in an unencrypted form.

Overview

By using a packet sniffer or software such as Network Monitor, anyone who can capture cleartext packets can read the information within them. Cleartext authentication methods are sometimes the best choice in a heterogeneous network environment where users running different operating system platforms need to access resources on network servers. For example, UNIX clients that need to access a Microsoft Internet Information Services (IIS) machine using a Web browser will need to be authenticated using a cleartext method called Basic Authentication.

Notes

Basic Authentication is usually described as cleartext authentication, but in actuality Basic Authentication weakly encrypts data using the well-known Uuencoding algorithm. This algorithm is in the public domain and can easily be decrypted by knowledgeable users.

The standard AppleTalk protocol uses clear-text authentication for allowing Apple Macintosh clients to access shared folders on Macintosh file servers using AppleShare.

ClearType

A new display technology from Microsoft Corporation designed for liquid crystal display (LCD) displays.

Overview

Microsoft ClearType is intended to provide more readable displays on LCD screens for laptops, tablet PCs, and Pocket PCs. ClearType does this by a process known as sub-pixel rendering, which triples the perceived number of pixels for vertical screen resolution (horizontal resolution remains unchanged). The results are easier-to-read text that appears more like a page out of a book than text displayed on a screen. ClearType was designed with Microsoft Reader in mind, a technology developed by Microsoft for eBooks.

ClearType technology was developed by Microsoft Research, but a similar subpixel rendering concept was developed in the 1970s by Steve Gibson for the Apple II platform. ClearType support will be included in all future releases of Microsoft Windows and Microsoft Office.

client

A workstation or computer, usually belonging to a single user, as opposed to a server, which is shared by many users.

Overview

Planning the hardware, software, configuration, deployment, and maintenance of clients is as important to the network administrator as the other server-related activities.

Choice of a client operating system depends on various considerations. For example, in determining whether to install Microsoft Windows Millennium Edition (Me), Windows 2000 Professional, or Windows XP Professional on client computers, users should consider the following:

- Both client operating systems, in conjunction with Microsoft Internet Explorer versions 5 and later, offer the same desktop configuration options, similar utilities, and similar support for features such as user profiles, hardware profiles, and system policies.
- Windows 2000 Professional or Windows XP Professional will provide client machines with better performance, greater reliability, and more robust security, but they have higher hardware requirements than Windows Millennium Edition (Me).
- Windows Me supports a broader range of devices and legacy software applications, and includes power-management support—making it a better solution for mobile users.

Notes

In configuring clients to operate on a network, appropriate software must be installed on each client to allow it to access servers on the network. For example, to access Windows 2000 servers, client machines require Microsoft client software such as Client for Microsoft Networks. To access Novell NetWare servers, client machines require NetWare-compatible clients, such as Client for NetWare Networks.

client access license (CAL)

A license that grants a client machine access to a Microsoft BackOffice product running on a network of computers.

Overview

Every client computer on a network, regardless of whether it is running a Microsoft or non-Microsoft operating system, requires a client access license (CAL) if it will be accessing any of the following Microsoft Windows NT, Windows 2000, Windows XP, or Windows .NET Server services:

- File services, for accessing shared files and folders on a server
- Print services, for accessing shared network printers
- Remote Access Service (RAS) or Routing and Remote Access Service (RRAS)
- File and Print Services for NetWare (FPNW)
- File and Print Services for Macintosh (FSM)
- Microsoft Transaction Server (MTS) and Microsoft Message Queue (MSMQ) Server access
- Windows NT Terminal Server functionality

Client access licenses can operate in one of two modes:

- Per Server licensing, which is based on concurrency of access to network resources
- Per Seat licensing, which is the more commonly implemented solution and is supported by all BackOffice applications

client certificate

A digital certificate obtained for a client application (such as a Web browser) that can be used by the client to digitally sign data it transmits.

Overview

Client certificates can be used to enable client machine authentication for the purpose of secure communication over the Internet using the Secure Sockets Layer (SSL) protocol.

Client certificate. Importing a client certificate in the Internet Explorer Properties dialog box.

A client obtains a certificate from a certificate authority (CA) by submitting a certificate request file. The CA responds by issuing a client certificate, which contains the client's identification information in encrypted form, along with the client's public key. The client certificate must then be installed on the client's Web browser. Microsoft Internet Explorer can import client certificates into the browser's certificate store using the Personal button on the Content tab of the Internet Options dialog box. Administrators can also use the Internet Explorer Administration Kit (IEAK) for pre-configuring client certificates prior to installation on user computers.

In SSL communication, a Web server can validate the identity of a client using the certificate installed on the client. With Microsoft Internet Information Server (IIS) version 4, client certificates can be mapped to Microsoft Windows NT user accounts by way of a process called certificate mapping. (Windows 2000, Windows XP, and Windows .NET Server support a similar feature in their Internet Information Services.) Certificate mapping makes it easier for administrators to control access to content located on the Web server.

Notes

Use client certificates when it is important for servers to validate the identity of clients—for example, when your enterprise includes mobile users with laptops who need

to remotely and securely access the company's intranet server using Internet Explorer.

Client for Microsoft Networks

A networking component in Microsoft Windows 95, Windows 98, Windows Millennium Edition (Me), Windows 2000, Windows XP, and Windows .NET Server that makes it possible to access file and print services on all of the above versions of Windows, as well as Windows NT, Windows for Workgroups, and LAN Manager dedicated servers and peer servers.

Overview

Client for Microsoft Networks works with any combination of NetBEUI, IPX/SPX-Compatible Protocol, and Transmission Control Protocol/Internet Protocol (TCP/IP) protocols. Client for Microsoft Networks cannot be used for accessing non-Microsoft servers such as Novell NetWare servers. You must install Client for NetWare Networks to access these servers. Windows 95 and Windows 98 allow you to install more than one client at a time to access different kinds of servers on the network.

Use the Network utility in Control Panel to install Client for Microsoft Networks on a computer running Windows 95 or Windows 98. Then use the property sheet of Client for Microsoft Networks to configure the computer to either participate in a workgroup or log on to a Windows NT, Windows 2000, or Windows .NET Server domain.

Notes

In Windows NT, the equivalent component is called the Workstation service, but in Windows 2000, Windows XP, and Windows .NET Server, the component is Client for Microsoft Networks, as in Windows 95 and Windows 98.

Client for NetWare Networks

In Microsoft Windows 95, Windows 98, Windows Millennium Edition (Me), Windows 2000, Windows XP, and Windows .NET Server, a networking component that makes it possible to access file and print services on Novell NetWare servers.

Overview

Client for NetWare Networks requires that the IPX/SPX-Compatible Protocol be installed. Client for NetWare Networks cannot be used for accessing Microsoft servers such as Windows NT, Windows 2000, and Windows .NET Server. You must install Client for Microsoft Networks to access these servers. Windows 95 and Windows 98 allow you to install more than one client at a time to access different kinds of servers on the network.

Use the Network utility in Control Panel to install Client for NetWare Networks on a computer running Windows 95 or Windows 98. Then use the property sheet of Client for NetWare Networks to configure the preferred NetWare server, to select the first drive letter to use for mapping network drives from NetWare command-line utilities, and to enable processing of logon scripts on the preferred server.

Notes

Client for NetWare Networks can connect to NetWare 3 and earlier servers, or NetWare 4 servers running in bindery emulation mode. If you want to use Client for NetWare Networks to connect to a NetWare 4 server running Novell Directory Services (NDS), you must also install Service for NetWare Directory Services on the Windows 95 or Windows 98 client. This service is available with Windows 95 OSR2 or Service Pack 1 for Windows 95, and is included with Windows 98.

Before installing Client for NetWare Networks on a computer running Windows 95 or Windows 98, make sure you remove any real-mode NetWare requestor software running on the machine, such as NETX (the NetWare 3.x client shell) or VLM (the NetWare 4.x client shell).

client installation point

A shared directory on a network file server to which users on your network can connect to install client software locally on their client computers.

Overview

Creating a client installation is the first step in preparing to install software over the network. To create a client installation point, create a directory on a server and share the folder with full permissions for administrators and read-only permissions for ordinary users. Either copy the installation files for the software from the CD to the shared directory, or run the setup program using a special switch to copy the files so that they can be used for network installation—for example, to uncompress the cabinet files on the CD. Users can then connect to the shared directory, run the setup program, and complete the installation process.

client/server

A paradigm for deploying two-tiered distributed applications.

Overview

In the client/server model, an application is split into a front-end client component and a back-end server component. The front-end client part of the application runs on a workstation and receives data that is input by the user. The client component prepares the data for the server by preprocessing it in some fashion, and then sends the processed information to the server, usually in the form of a request for some service. The back-end server component receives the client's request, processes it, and returns information to the client. The client receives the information returned from the server and presents it to the user by way of its user interface. Usually most of the processing is done at the back end (server end) where database servers, messaging servers, file servers, and other resources are located.

An example of a simple client/server application is a Web application that is designed for Microsoft Internet Information Services (IIS) using a combination of server-side Active Server Pages (ASP) programming and client-side scripting. The ASP scripts run on the Web server, while the client-side scripts run on the client Web browser.

Client Services for NetWare (CSNW)

A Microsoft Windows 2000, Windows XP, and Windows .NET Server service that provides Windows clients with access to Novell NetWare file, print, and directory services.

Overview

Client Services for NetWare (CSNW) is an optional service that can be installed on Windows 2000, Windows XP, and Windows .NET Server machines to enable them to directly connect to file and print resources on Novell NetWare servers. In other words, CSNW is a Microsoft version of the NetWare redirector for Windows 2000, Windows XP, and Windows .NET Server.

Client Services for NetWare (CSNW). How CSNW works.

CSNW is a full-featured, 32-bit client for NetWare networks that can be installed on Windows 2000 Professional or Windows XP Professional by using the Network and Dial-Up Connections utility in Control Panel. If you are connecting to a NetWare 3.12 or earlier server, you must specify a preferred NetWare server for access to its bindery. If you are connecting to NetWare 4, specify the Novell Directory Services (NDS) tree and default context. CSNW supports browsing NDS trees, but it does not support administration of NDS trees.

CSNW supports connections to servers running version 2, 3, or 4 of NetWare, including both bindery emulation and NDS on NetWare 4. CSNW includes support for NetWare Core Protocol (NCP), Large Internet Protocol (LIP), and Long filenames (LFNs). Additional options are included for printing and login script support. CSNW requires installation of the NWLink protocol, but if it is not installed already, it will be added automatically when you install CSNW on a machine.

Notes

On a machine running Windows 2000 Server, NetWare connectivity is provided by Gateway Services for NetWare (GSNW). Use CSNW to provide your Windows 2000 Professional or Windows XP Professional clients with dedicated access to Novell NetWare servers; use GSNW only to provide occasional access to NetWare servers from Windows 2000 Professional or Windows XP Professional clients.

An alternative to using CSNW on Windows 2000 Professional machines is to use the Novell Client for Windows 2000.

cloud

In networking, any part of the network whose data transmission paths are unpredictable and vary from session to session.

Overview

Clouds are often used in networking diagrams to represent packet-switching services. In these services, a packet sent from one node to another follows an unpredictable path because, at any given moment, different routers or other devices can be used to forward the packet toward its destination. The Internet is an example of a packet-switching cloud for Transmission Control Protocol/Internet Protocol (TCP/IP) networking because data sent between two points can travel over many possible paths. This is why the Internet is graphically represented as a cloud in drawings of wide area networks (WANs). Other examples of packet-switching services include frame relay and X.25 networks.

Cloud. The Internet depicted as a cloud of paths and connections.

Circuit-switched services are often represented as clouds as well. In circuit-switched services, communication switches at various telco and carrier central offices (COs) and switching facilities are temporarily used for establishing circuits between two communicating nodes. Each time communication is terminated and reestablished, different sets of switches can be used.

cluster

A group of two or more nodes within a system supporting clustering.

Overview

When a client on a network tries to access shared resources or applications on a cluster, the cluster appears to the client as a single node or server instead of the group of nodes or servers it really is.

In the Cluster service of Microsoft Windows 2000 and Windows .NET Server Enterprise Server and Datacenter Server, each node in a cluster is a completely independent computer system that must be running Windows 2000 Enterprise Server. Typically, such nodes are connected by a shared storage bus such as an external Small Computer System Interface (SCSI) disk subsystem or RAID array.

cluster-aware application

An application that can run on a node of a cluster and can be managed as a cluster resource.

Overview

In the Cluster service on Microsoft Windows 2000 or Windows .NET Server Enterprise Server and Datacenter Server editions, a cluster-aware application is one that can run on a node of a cluster and can be managed as a cluster resource. Cluster-aware applications can be written to access the Windows 2000, or Windows .NET Server Cluster service by using its cluster application programming interface (API). Cluster-aware applications also implement the extension dynamic-link libraries (DLLs) of Cluster Administrator, which allow them to be managed using Cluster Administrator. These features allow developers to write high-scalability applications that can operate across the different nodes in a cluster.

A cluster-aware application is one that is aware of the fact that it is running on a cluster and can make use of the scalability, load balancing, and failover aspects of clustering to provide high availability for mission-critical business environments. Cluster-aware applications include database applications such as Microsoft SQL Server, messaging applications such as Microsoft Exchange Server, and Web applications for running on Web servers such as Microsoft Internet Information Services (IIS).

clustering

Any technology that enables two or more servers to appear to clients as a single system.

C**Overview**

A cluster consists of a group of computers functioning together as a unit, running a common set of applications, and presenting a single image to client systems. Clustering can be implemented in various ways, but its basic goals are to provide businesses with high availability, high reliability, and high scalability solutions for mission critical business operations.

Clustering solutions generally come in two basic types:

- **Stateful clustering:** The goal of this type of clustering is to provide high availability and high reliability for fast, uninterrupted service in high-demand environments that can tolerate minimal downtime (stateful clustering is not designed to scale applications out to handle more users—this is the purpose of stateless clustering discussed next). Stateful clustering works by connecting independent computer systems into a single entity called a cluster, with each system within the cluster being called a node. Generally some multiple of two is used as the number of nodes within a cluster, for example, 2, 4, 8, 16, or 32 nodes. The different nodes within a cluster are usually connected using a shared disk subsystem which typically consists of a hard disk system or RAID-5 array connected to each node using a fast Small Computer System Interface (SCSI) bus or fiber channel connection. The result is a cluster of computer systems that acts and functions as if it were a single system. In stateful clustering, the nodes within a cluster generally share the workload, and when one node fails its workload fails over (transfers to) another node in the cluster with no interruption of services from the user's perspective. When the failed node comes back online, the workload fails back to this node and normal operation of the cluster resumes. Failover in stateful clustering systems can be implemented in different ways, and this is discussed below. An example of a platform supporting stateful clustering is the Cluster service of Microsoft Windows 2000 Enterprise Server and Datacenter Server. Another name for stateful clustering is shared storage or shared something clustering.
- **Stateless clustering:** The goal of this type of clustering is to provide high availability and high reliability by enabling administrators to scale out applications to meet increased demand as the number of users and traffic generated increase. Stateless clustering uses a group of nodes (servers) that are not connected in any way apart from the underlying network connectivity. No failover occurs between nodes when a node in the cluster fails. Instead, some form of load balancing is used to share the workload between the different nodes, and if one node fails the other nodes pick up the extra workload with no interruption of services. Stateless clustering is supported by three Microsoft products: Network Load Balancing (NLB), Component Load Balancing (CLB), and Application Center 2000. Another name for stateless clustering is shared-nothing clustering, and SQL Server 2000 supports a form of shared-nothing clustering known as Federated Server Groups.

Stateful clustering solutions themselves generally fall into three different categories, depending on if and how failover occurs between different nodes:

- **Active/active clustering:** This type of clustering makes the most efficient use of system resources because there are no redundant nodes: all nodes run active processes. If one node of a cluster fails, other nodes take on the failed cluster's workload. The latency for failover in this scenario is typically 15 to 150 seconds, depending on the hardware/software configuration. Active/active clustering is supported by the Cluster service of Microsoft Windows 2000 Enterprise Server and Datacenter Server, and by the Cluster service of Windows .NET Server (discussed later in this article).
- **Active/standby clustering:** Nodes are paired within a cluster, with one node designated to take over should another node fail. If an active node fails, a standby node assumes its workload. Latency for failover is also 15 to 150 seconds. Active/standby clustering is a more expensive solution than active/active because the standby node is essentially doing nothing unless the active node fails.

- **Fault-tolerant clustering:** Nodes are paired within a cluster, and all nodes perform all tasks simultaneously. This is an expensive solution from a hardware point of view, but latency for failover is reduced to a second or less.

Marketplace

Many different clustering solutions are in the marketplace, but this article focuses on four different clustering technologies delivered by Microsoft platforms and products, namely:

- Windows clustering, previously known as Microsoft Cluster Services (MCSC)
- Network Load Balancing (NLB)
- Application Center 2000
- Component Load Balancing (CLB)

You can find additional information in separate articles on each of these four solutions.

Windows clustering is a feature of Microsoft Windows 2000 Advanced Server and Datacenter Server and of Windows .NET Server. Windows clustering is probably Microsoft's best-known clustering platform and was originally developed for Microsoft Windows NT Server Enterprise Edition where it was code-named Wolfpack during its development. Windows clustering is a stateful clustering solution that enables system architects to create clusters from groups of independent computer systems and to run and manage cluster-aware applications. Using Windows clustering, you can build two-way clusters (that is, clusters with only two nodes) on Windows 2000 and Windows .NET Server Enterprise Server edition or four-way clusters on Windows 2000 and Windows .NET Server Datacenter Server edition (Windows NT Server Enterprise Edition supported only two-way clustering). In Windows clustering a cluster connects nodes together using a shared file system and clusters can utilize active/active clustering for maximum reliability and availability. Windows clustering makes an excellent choice for clustering database and messaging applications for enterprises.

Network Load Balancing (NLB) is a stateless clustering solution included with Windows 2000 and Windows

.NET Server Enterprise Server and Datacenter Server editions, and it was formerly called Windows Load Balancing Services (WLBS) on the Windows NT Server 4 platform. NLB provides load balancing of Internet Protocol (IP) traffic to up to 32 independent network nodes (servers) and is typically used to build farms of Web servers or Exchange 2000 Outlook Web Access (OWA) servers for large enterprises. When one node in an NLB cluster goes down, the load is simply redistributed to the remaining nodes.

Application Center 2000 is a part of Microsoft Corporation's .NET Server family, and is a stateless clustering platform designed to provide a single point of management for farms of Web servers. Appcenter is typically used in conjunction with NLB and CLB to provide high availability, high reliability clustering that can scale out to large numbers of users. Appcenter manages a collection of servers in a Web farm as a single entity and can be used to create new clusters, join servers to existing cluster, remove nodes from clusters, deploy applications and application components to different nodes within a cluster, move components between nodes of a cluster, monitor the performance of a cluster, and manage load balancing of network connections to cluster nodes and COM+ components within a cluster-aware application.

Component Load Balancing (CLB) is supported by all versions of Windows 2000 Server and is used to provide load balancing of COM+ objects across distributed applications deployed on up to 16 nodes (servers). CLB is a stateless clustering solution that requires no special hardware but needs Microsoft Application Center 2000 in order to operate.

CN

Stands for connected network; in Microsoft Message Queue (MSMQ) Server terminology, a name for a collection of computers in which any two computers can directly communicate.

See: *connected network (CN)*

CNAME record

Stands for Canonical Name record, a Domain Name System (DNS) resource record for assigning an alias to a host.

Overview

A CNAME record is used to map an alias to the canonical name (true name) of a host on the Internet or a private Internet Protocol (IP) internetwork. The CNAME record thus lets you use more than one name to refer to a single host on the network. If a name server is queried by a resolver to look up a host and the queried name is an alias in a CNAME record, the name server replaces the alias name with the canonical name of the host being looked up and then looks up the address of the canonical name.

Examples

Here is an address record for the host named server12 in the microsoft.com Internet domain. This record has the IP address 172.16.8.5, followed by a CNAME record indicating that the name bobby (or the fully qualified domain name bobby.microsoft.com) is an alias for the same host:

```
server12.microsoft.com IN A 172.16.8.55
bobby IN CNAME server12
```

Uses

CNAME records are generally used to hide the true names of important servers on your network from the outside world.

CNRP

Stands for Common Name Resolution Protocol, a proposed Internet Engineering Task Force (IETF) standard for a protocol to replace Uniform Resource Locators (URLs) with a simpler, more natural scheme for navigating the Web.

coax

Short for coaxial cabling, a legacy form of network cabling.

See: *coaxial cabling*

coaxial cabling

A legacy form of network cabling.

Overview

Coaxial cabling (or simply coax) is a form of network cabling that was used in legacy 10Base2 and 10Base5 Ethernet networks. The name *coax* comes from its two-conductor construction in which the conductors run concentrically with each other along the axis of the cable. Coaxial cabling in local area networks (LANs) has been largely replaced by twisted-pair cabling (structured wiring installations) within buildings, and by fiber-optic cabling for high-speed network backbones.

Coaxial cabling. Typical coax cabling.

Coaxial cabling generally consists of a solid copper core for carrying the signal, covered with successive layers of inner insulation, aluminum foil, a copper braided mesh, and outer protective insulation. A solid conductor provides better conductivity than a stranded one, but is less flexible and more difficult to install. The insulation is usually polyvinyl chloride (PVC) or a non-stick coating; the aluminum foil and copper mesh provide shielding for the inner copper core. The mesh also provides the point of grounding for the cable to complete the circuit.

Types

Coaxial cabling comes in various types and grades. The most common are the following:

- Thicknet cabling, which is an earlier form of cabling used for legacy 10Base5 Ethernet backbone installations. This cabling is generally yellow and is referred to as RG-8 or N-series cabling. Strictly speaking, only cabling labeled as IEEE 802.3 cabling is true thicknet cabling.
- Thinnet coaxial cabling, which is used in 10Base2 networks for small Ethernet installations. This grade of coaxial cabling is generally designated as RG-58A/U cabling, which has a stranded conductor and a 53-ohm impedance. This kind of cabling uses bayonet Neill-Concelman (BNC) connectors for connecting to other networking components, and must have terminators at free ends to prevent signal bounce.
- ARCNET cabling, which uses thin coaxial cabling called RG-62 cabling with an impedance of 93 ohms.
- RG-59 cabling, which is used for cable television (CATV) connections.

In addition, a number of special types of coaxial cabling are sometimes used for certain networking purposes. An example is twinax cabling, which consists of two conductors first enclosed in their own insulation and then enclosed in a single copper mesh and insulating jacket. Twinax is used in legacy IBM networks for connecting AS/400 systems to 5250 terminals. Other more exotic varieties include triax, quadrax, and ribbon types of coaxial cables.

Notes

Coaxial cabling is often used in heavy industrial environments where motors and generators produce a lot of electromagnetic interference (EMI), and where more expensive fiber-optic cabling is unnecessary because of the slow data rates needed. Coaxial cabling is also used frequently in IBM mainframe and minicomputer environments. A device called a splitter can be used to fork one coaxial cable into two—for example, when connecting two 3270 terminals to one IBM mainframe system. A splitter is used at either end of the connection so that the signals for both terminals can be sent over a single coaxial cable. Coax multiplexers can be used to connect eight or more terminals to a single controller.

codec

Short for **compressor/decompressor**, an encoding algorithm used for recording digital audio or video.

Overview

A codec compresses transmitted data at the sending end and decompresses it at the receiving end. Microsoft Windows Media Player uses different codecs to provide streaming multimedia information over a Transmission Control Protocol/Internet Protocol (TCP/IP) network such as the Internet. Windows Media Player provides a number of different codecs for different purposes. You can select a codec to give you the audio or image quality and image size that you want for your transmission.

Code Division Multiple Access (CDMA)

A second-generation (2G) digital cellular phone technology popular in the United States and parts of Asia.

Overview

Code Division Multiple Access (CDMA) can be used to refer both to a type of digital cellular phone system and to the specific media access method used by this kind of cellular system. CDMA was developed by QUALCOMM in 1993, and it was adopted and ratified by the Telecommunications Industry Association (TIA) as part

C

of their Interim Standard 95, specifically as TIA standard IS-95a.

CDMA supports combined voice and data over a single channel and supports circuit-switched data transmission at a rate of 14.4 kilobits per second (Kbps), although in practice speeds are more typically around 13 Kbps. Speeds up to 19.2 Kbps are also possible by using special error detection and correction techniques.

Architecture

CDMA uses the spread spectrum wireless networking technology—first developed for military communication systems in the 1940s because it spreads its transmission over a large bandwidth, making it difficult to jam. Instead of dividing the available radio spectrum into a series of discrete channels using the older Time Division Multiple Access (TDMA) media access method, a CDMA channel occupies the entire available frequency band. In other words, all CDMA users on a given network utilize the same frequency band.

What enables users to share the same spectrum is that CDMA assigns a special digital code sequence to each user. Users thus share time and frequency resources on the available bandwidth, and their individual communications are channeled using these codes. The code tag identifies the conversation to the transmission station and enables multiple users to simultaneously access the network and divide its frequency resources between them—hence the name Code-Division Multiple Access.

Without knowledge of a conversation's code tag, eavesdropping on CDMA conversations is difficult, making CDMA a more secure cellular phone technology than the Advanced Mobile Phone Service (AMPS) still used widely in the United States. CDMA also has a much higher call capacity than AMPS and is comparable to the Global System for Mobile Communications (GSM) standard for cellular communication used in Europe. The disadvantage is that CDMA is more complex to implement than TDMA digital cellular technologies.

Marketplace

The main CDMA-based system in the market today is QUALCOMM's cdmaOne, the operation of which is now supervised by the CDMA Development Group and independent organization. The cdmaOne system uses 64 different codes called Walsh sequences, and in theory thus supports up to 64 concurrent users talking over a single 1.25-megahertz (MHz)-wide channel. In practice, however, this works out to more like 20 concurrent users, especially when data transmissions are included. The cdmaOne system has approximately 30 million users in the United States and Asia, with its competitors being Global System for Mobile Communications (GSM), which has 150 million users worldwide; Digital Advanced Mobile Phone Service (D-AMPS), with 15 million users in the United States; and Personal Digital Cellular (PDC), with 45 million users in Japan.

A special upgrade to cdmaOne called IS-95b provides improved data speeds of up to 115 Kbps, though real speeds are usually more like 64 Kbps (the version of IS-95b in Japan and Korea supports packet-switched data rates of only 64 Kbps). Further proposed 2.5G and third-generation (3G) improvements fall under the umbrella name of CDMA2000, and the CDMA technology itself forms the basis of much of the proposed IMT-2000 standard for 3G cellular communications from the International Telecommunication Union (ITU).

Another cellular system in the United States based on CDMA technologies is Sprint PCS from Sprint Corporation, which operates at a higher frequency band than cdmaOne but uses CDMA as its media access control method.

Notes

CDMA does not assign specific frequencies to each user as do other competing systems. Instead, CDMA uses a unique technique where every channel uses the entire available spectrum. CDMA was developed and first used by the military during World War II by the English to thwart German attempts at jamming transmissions. The Allies utilized CDMA to transmit over

different frequencies, instead of one, which made it extremely difficult for the Germans to pick up entire signals.

Coded Orthogonal Frequency Division Multiplexing (COFDM)

A technique for enhancing the speed of wireless networking.

Overview

Coded Orthogonal Frequency Division Multiplexing (COFDM) is employed by the 802.11a wireless networking standard as a way to work around the difficulty of radio frequency (RF) interference caused by scattering and reflection off of buildings, walls, and similar objects. The problem with wireless networking, as opposed to wireline (wired) networking, is that although wireline networks usually have a single path between different stations, wireless communication is often multipath. As the figure shows, a signal can travel between a wireless client and a base station along different paths due to reflection of RF signals off walls and other objects. The result is that when the signal arrives it is spread out in time. If the time over which a signal can be spread out by interference (the delay spread) is less than the time between individual packet transmissions (the symbol rate), then the receiver can still be processing one packet while the next one arrives, creating a problem.

COFDM works around this problem not only by slowing down the symbol rate (the rate of packet transmission) but also by cramming as much information as possible into each packet. COFDM thus transmits data in a massively parallel fashion, ensuring that each symbol can be processed in a time less than the delay

spread between divergent signal paths. Each symbol transmitted is preceded and followed by a cyclic prefix called a guard interval, which helps give the baseband processor time to receive and process the information. Additional error-correcting information is encoded to help reduce the effects of interference.

Coded Orthogonal Frequency Division Multiplexing (COFDM). COFDM helps overcome the delay spread caused when signals are reflected off of interfering objects.

Using COFDM, wireless networks based on 802.11a can break through their current speeds of 10 to 20 megabits per second (Mbps) to achieve speeds of 155 Mbps or even higher.

code-operated switch

A switch with a combination of input and output ports, the connections between which can be remotely reconfigured by commands entered into a computer.

Overview

Code-operated switches are useful in environments where remote switching is needed for file-sharing or monitoring purposes. For example, you could use an RS-232 serial code-operated switch to remotely switch between pieces of data terminal equipment (DTE), such as servers or routers for running diagnostics from a remote console.

Code-operated switch.

Implementation

Internal dual inline package (DIP) switches are usually used to configure the code-operated switch so that a different arming character can be used to trigger each connected device. The code-operated switch then examines the incoming data stream for these special text-string codes in order to determine to which device it should route data. An example might be the remote switching between printers. A remote computer could send an embedded switching character to specify which printer connected to the code-operated switch should be used for printing the data.

A remote user can connect to the company network using a modem that interfaces with a code-operated switch, and then use the switch to control a variety of serial-controlled devices in an industrial environment, such as a group of laboratory instruments. Code-operated switches are available from different vendors in configurations supporting up to 64 different serial devices from one remote connection.

Besides embedding switching characters in the data stream, embedded control characters can also be used to directly control the code-operated switch.

cold boot

Restarting the computer by turning the power switch off and then on, or by shutting down the computer, turning it off, and then turning it on again.

Overview

If you perform the first type of rebooting, open files will not be properly closed and data can be lost. However, this method ensures that memory is cleared and devices are properly reset. An example might be when you reconfigure the settings of a legacy modem using the modem utility in Control Panel. You might find that you must cold boot your machine in order for the new configuration settings to fully take effect.

Cold Fusion

A popular tool for developing dynamic Web applications.

Overview

Cold Fusion from Allaire Corporation lets developers rapidly create and deploy dynamic Web applications that can access information from databases and other data sources. Cold Fusion uses a set of proprietary tags that are similar to Hypertext Markup Language (HTML) tags. The resemblance to HTML tags makes Cold Fusion a comfortable platform for experienced HTML users to develop database-driven applications that can be accessed from Web browsers. Cold Fusion is available for both UNIX and Microsoft Windows platforms, and it is an alternative to Microsoft Corporation's Active Server Pages (ASP) technology for developing dynamic Web applications.

Collaboration Data Objects (CDO)

A collection of Component Object Model (COM) objects that allow developers to create Microsoft Internet Information Services (IIS) Web applications that send and receive electronic mail.

Overview

Collaboration Data Objects (CDO) is a Microsoft object library that provides messaging capability for applications written in Microsoft Visual Basic, Microsoft Visual C++, and Win32 Virtual Machine for Java. CDO provides distributed Web applications with a standard way to quickly and easily create, send, post, receive, read, and manipulate messages using interfaces based on standard Internet protocols such as Simple Mail Transfer Protocol (SMTP), Network News Transfer Protocol (NNTP), and Multipurpose Internet Mail Extensions (MIME).

CDO was formerly known as Active Messaging, and on the Microsoft Windows NT platform was called Collaboration Data Objects for Windows NT Server (CDONTS). CDONTS actually provides a subset of

CDO functionality that includes messaging services but omits the calendaring and workflow functions that CDO on Microsoft Exchange 2000 provides.

CDO 2 is included with IIS in Windows 2000, Windows XP, and Windows .NET Server to support the built-in SMTP and NNTP services. CDO 2 does not support mailboxes, but it does support protocol events to enable programmers to write routines that respond to incoming messages and process outgoing messages. Developing mail-enabled applications using CDO is easier and faster than building custom Common Gateway Interface (CGI) mail programs, and CDO applications have more flexibility than typical CGI applications.

CDO is also a powerful development tool for Exchange Server 2000 and is the premier application programming interface (API) for building collaborative solutions using Exchange. CDO in Exchange 2000 consists of three components:

- **CDO for Exchange 2000:** Used for building collaborative solutions that make use of e-mail, contact management, and scheduling.
- **CDO Workflow Objects for Exchange:** Used to build workflow and routing applications.
- **CDO for Exchange Management:** Used for creating and managing mailboxes and recipients.

Notes

For security reasons, scripts running on Microsoft Internet Explorer cannot access CDO.

collapsed backbone

An enterprise networking methodology in which the network backbone consists of a single device.

Overview

In a traditional network, local area networks (LANs) are multipoint connections connected using a backbone cable. For example, in a building, a fiber-optic backbone might run from floor to floor and connect with a hub in a wiring closet on each floor. In contrast, collapsed

C

backbones make use of centralized switches, which provide virtual point-to-point connections for LAN connections. These switches are located in the same place as the network servers—in fact it was the move toward centralized location of network servers that helped drive the development of collapsed backbones.

In a typical collapsed backbone scenario, instead of having a hub for each floor located in that floor's wiring closet, a set of stackable Ethernet switches would be located in the equipment room in the basement, with individual cables running from this closet through vertical risers to wiring closets on each floor where hubs distribute connections to stations in work areas.

Advantages and Disadvantages

The advantages of using a collapsed backbone are that they eliminate the costs of backbone cabling installation, they require fewer devices, their equipment administration is more centralized, and they offer higher available bandwidth for each station. The disadvantages are that collapsed backbones generally are not feasible for use in more than one building, they require more cabling, they use more expensive devices, and they have a more limited distance capability.

collision

A condition that occurs when two or more computers on a network try to transmit signals over the same wire at the same time.

Overview

Collisions are inevitable on a network as long as there is more than one computer on the network. Handling collisions is one of the main functions of a network access method. For example, in Ethernet networks, collisions often occur when two or more stations attempt to place frames on the wire at the same time. To handle this situation, Ethernet uses the access method called Carrier Sense Multiple Access with Collision Detection (CSMA/CD).

When a station begins transmitting a signal and detects a collision, the station stops transmitting and issues a jam signal to tell the other station that a collision has

occurred. Both stations then stop transmitting and wait a random length of time before retransmitting their signals. The amount of time the stations wait before retransmitting increases with the number of collisions occurring on the network.

See Also: Carrier Sense Multiple Access with Collision Detection (CSMA/CD), collision domain, Ethernet

collision domain

An area of a network where signals transmitted by different stations with that area can collide.

Overview

In Carrier Sense Multiple Access with Collision Detection (CSMA/CD) networks such as Ethernet, a collision can occur if two computers on the network attempt to transmit signals at the same time. When a collision occurs, the network is momentarily offline and no computers can communicate on it.

The larger the collision domain of an Ethernet network, the more computers present and the higher the probability of collisions occurring and negatively affecting network performance. When collision domains become too large, so many collisions occur that network communications become possible. As a result, it is important to segment Ethernet networks to keep collision domains small enough that the effect of collisions is minimized on the network.

Segmenting a collision domain can be accomplished using bridges, switches, routers, and other devices. For example, if two Ethernet hubs are connected directly to a third hub, the resulting local area network (LAN) is still only a single collision domain because only hub connections are used between segments of the network. But if the two hubs are directly connected to an Ethernet switch, you have two collision domains because the switch enables the two networks to function independently. Routers also segment networks into broadcast domains to prevent the occurrence of broadcast storms.

COM

Stands for Component Object Model, an object-based software architecture developed by Microsoft Corporation that allows applications to be built from binary software components.

See: Component Object Model (COM)

COM+

An extension of Microsoft Corporation's Component Object Model (COM).

Overview

COM was originally designed for building component-based applications to run on single systems. Distributed COM (DCOM) was an evolution of COM that enabled COM components to reside on different machines and communicate with each other over the network. COM+ takes DCOM a step further by providing services and features that enable large, distributed, multitier applications to be built for enterprise-wide systems and the Internet.

COM+ is part of the Microsoft Windows Distributed Network Architecture (DNA) programming paradigm. The COM+ that is supported by the Microsoft Windows 2000, Windows XP, and Windows .NET Server operating system platforms is basically COM plus Microsoft Transaction Server (MTS) and Microsoft Message Queue Server (MSMQ), minus some legacy COM functionality no longer needed. Some of the enhancements of COM found in COM+ include the following:

- Dynamic load balancing, which distributes client requests across multiple equivalent COM components
- Registration of COM+ objects that is cached in memory to speed up the process of locating and instantiating components
- In-memory database (IMDB), which provides quicker data access to applications by lowering overhead

- Publish and subscribe services, which provide an event mechanism enabling multiple clients to subscribe to published events and send notification to subscribers when events are fired
- Integration of Microsoft Message Queue Server (MSMQ) to support queued asynchronous calls issued to COM components, which let clients invoke methods on COM components using an asynchronous model for increased reliability over poor network connections and in disconnected usage scenarios
- Integration of Microsoft Transaction Server (MTS) into COM, which supports attribute-based programming, improvements in transactions, security and administration services, and improved interoperability with other transaction environments through support for the Transaction Internet Protocol (TIP)
- Inclusion of basic COM services in the COM+ runtime to simplify and speed up application development.

COM component object

A compiled software component based on Microsoft Corporation's Component Object Model (COM) technology.

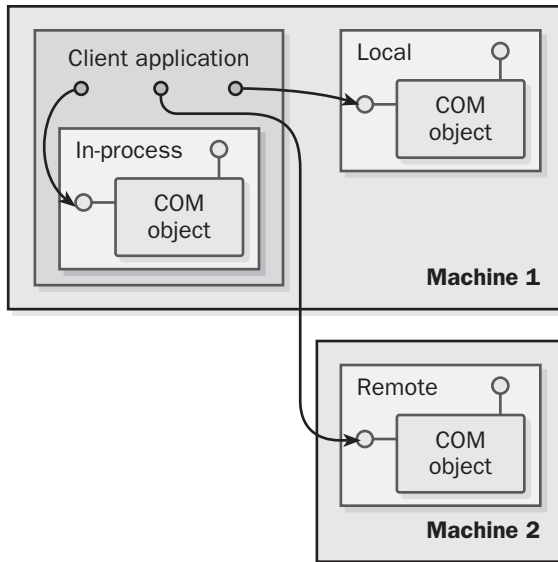

Overview

COM components generally refer to the physical files that contain the classes that define COM objects. COM components also include additional code, such as code to register the component in the registry and code for loading the component.

COM components can be written in many languages using tools such as Microsoft Visual Basic, Microsoft Visual J++, Microsoft Visual C++, and Microsoft Visual FoxPro. COM components that support Automation can be called by scripting languages such as Microsoft Visual Basic, Scripting Edition (VBScript) or Microsoft JScript.

C

COM component object. *In-process, local, and remote COM components.*

COM components can be run on an application server, a Web server, a Microsoft Transaction Server (MTS), or a client. COM components can be stand-alone applications or reusable software components, and they make the development of Web applications comparable to the development of system applications.

COM components interact with each other and with user applications in a client/server fashion. The client therefore uses the functionality of the server component by creating instances of classes that the server component provides and calling their properties and methods.

COM components can be designed to run in three different modes:

- **In-process:** The component executes in the calling application's process space.
- **Local:** The component executes in its own process space.
- **Remote:** The component executes in a process space on another machine.

An in-process COM component has the extension .ocx or .dll, while an out-of-process COM component (one running outside the calling application process) has the

extension .exe. COM components can run on another machine in a manner transparent to the calling application by using the Distributed Component Object Model (DCOM).

When developing applications based on COM components, use in-process components to optimize the speed of object access but use out-of-process components to maximize thread safety.

command

A method by which actions can be performed on a computer running Microsoft Windows by typing text into a command prompt window. The commands that are available depend on which version of Windows is used.

Overview

Examples of commands common to most Windows platforms include the Attrib command, Cacs command, Copy command, Dir command, and Diskcopy command. In addition to these Windows commands, some special commands are available only when certain networking services or protocols are installed. For example, if Transmission Control Protocol/Internet Protocol (TCP/IP) is installed on a computer running Windows, a number of TCP/IP commands are available, including the Arp command, Ping, Tracert, and Nbtstat.

Commands are useful for administering different aspects of a system or network using a command-line interface, such as a telnet connection or a command prompt. Commands are also often used in writing batch files that can perform a group of operations on a system or network service. You can run such a batch file directly, or you can schedule its operation for a predetermined time.

Finally, many Windows programs can be started in different ways from the command prompt using optional switches. For example, Windows Explorer can be run by typing explorer.exe from the command prompt. These programs are normally run using a graphical user interface (GUI), are started by desktop shortcuts, and are not usually referred to as commands.

command interpreter

The underlying service or daemon that supports a command-line interface.

Overview

The command interpreter is a system process that allows users to type text commands into the command line or command prompt and execute them to perform various routines and manage system and networking resources. Traditional UNIX systems make heavy use of the command line, while MS-DOS, the legacy Microsoft operating system, is basically a command shell for running text-based commands to control operating system processes.

On Microsoft Windows 2000, Windows XP, or Windows .NET Server systems, users can open a command prompt window to issue text-based commands to the underlying command interpreter Cmd.exe. These text-based Windows commands represent only a subset of the full functionality of the GUI-based administration tools available on the Windows 2000, Windows XP, and Windows .NET Server platforms.

The command interpreter is sometimes referred to as the operating system shell, especially on UNIX platforms. Entering a command into the command interpreter is referred to as “working at the command line.”

command line

A general name for any user interface that allows text-based commands to be entered and executed on a system. The term *command line* is popular in UNIX environments, but Microsoft Windows systems use *command prompt* to mean essentially the same thing.

See Also: *command interpreter, command prompt*

command prompt

A Microsoft Windows application that allows text-based Windows commands to be entered and executed.

Overview

The Windows command prompt provides a command-line interface (CLI) similar to those provided by UNIX systems. The command prompt can be used for

running operating system tasks, configuring networking services, and even accessing resources and applications over the network. Many common administrative tasks can be performed from the command prompt, although the command prompt itself provides a more complex and less intuitive interface than the usual desktop graphical user interface (GUI) of Windows operating systems. However, administrators who have spent significant time working in UNIX networking environments often find the command prompt a more familiar paradigm for administering a Windows-based network.

Command prompt. The command prompt in Windows 2000.

Notes

In Windows 2000, Windows XP, and Windows .NET Server, the command prompt application is Cmd.exe, located in the %SystemRoot%\system32 folder. In Windows Millennium Edition (Me), it is called the MS-DOS prompt, has the executable filename Command.com, and is in the \Windows folder. The Windows 2000, Windows XP, and Windows .NET Server versions can be configured using the Console utility in Control Panel.

For security reasons, should you wish as an administrator to disable the command prompt on a Windows 2000, Windows XP, or Windows .NET Server machine, you can accomplish this by either renaming Cmd.exe to something only you yourself are aware of, set NTFS file system (NTFS) permissions so that only Administrators can access it, or (not recommended) delete Cmd.exe entirely from the system.

Commerce Server 2000

Microsoft Corporation's platform for building and managing e-commerce solutions.

Overview

Commerce Server 2000 reduces the time it takes to develop and deploy complex e-commerce solutions. Commerce Server is based on Microsoft Site Server version 3 Commerce Edition (SSCE), and it builds on the strength of this earlier product. Commerce Server is part of the Microsoft Windows .NET Server family.

Commerce Server provides core services for managing your e-commerce site, including

- **Profile system:** Used to profile and manage customers and trading partners
- **Product catalog system:** Lets you manage millions of different products and find them quickly
- **Targeting system:** Lets you target customers with personalize one-on-one marketing
- **Business processing pipelines system:** Lets you customize your products to meet your customers' needs

In addition to these services, Commerce Server includes administration and development tools for building and managing your site, sample e-commerce sites you can use as templates and models, a data-warehousing decision-making system, help-desk customer support functionality, and much more.

commercial service provider (CSP)

Internet service providers (ISPs), online service providers, telephone and cable network operators, and other companies.

Overview

CSPs provide software services such as community access to mail, news, chat, and conferencing services. By

utilizing these services of a CSP, customers do not have to acquire licenses for the software the CSP provides.

Committed Information Rate (CIR)

A way of guaranteeing bandwidth in frame relay services.

Overview

Committed Information Rate (CIR) provides a way of guaranteeing minimum bandwidth for frame relay customers. Because customers on a frame relay network share the network, it is possible that service providers might oversubscribe the service—with the result that some customers receive insufficient bandwidth. Another situation where this can be a problem is if many customers try to access the frame relay network at the same time.

CIR guarantees that data throughput on frame relay connections will not drop below a previously agreed-upon contractual lower limit. However, CIR does permit short bursts of traffic to occupy greater amounts of bandwidth.

Common Desktop Environment (CDE)

A graphical user interface (GUI) or desktop environment developed for UNIX systems.

Overview

Common Desktop Environment (CDE) was developed by IBM, Sun Microsystems, and Hewlett-Packard under the Common Open Software Environment (COSE) initiative. CDE is a paradigm that is widely used in the UNIX industry. CDE is based on various industry standards including the X Window System (X11) release 5, X/OPEN, OSF/Motif 1.2, and others.

CDE is designed to provide UNIX users with a simple and consistent desktop interface that includes

- Standard Windows-management features

- File-system browsing tools supporting multiple views
- Customizable user interface—management tools for changing backdrops, mouse and keyboard settings, and screen savers
- Extensive and easily accessed online help features
- Multiple workspaces for increasing available desktop area

Common Gateway Interface (CGI)

A mechanism by which a Web browser can request a Web server to execute an external application.

Overview

Common Gateway Interface (CGI) was developed in the UNIX networking environment to allow Web browsers to execute “gateway” applications on Web servers. These gateway programs are typically written either in a compiled language such as C or in an interpreted language such as Perl. CGI allows Web servers to run scripts or programs on the server and send the output to the client Web browser, thus turning the Web into a platform for running dynamic applications instead of merely presenting static information to clients.

Architecture

CGI programs are called “gateway” programs because the Web server passes the CGI request to the external program, which then runs as a separate process to

process the input data, generate the results, and pass these results back to the Web server, which then returns them properly formatted in Hypertext Markup Language (HTML) to the client.

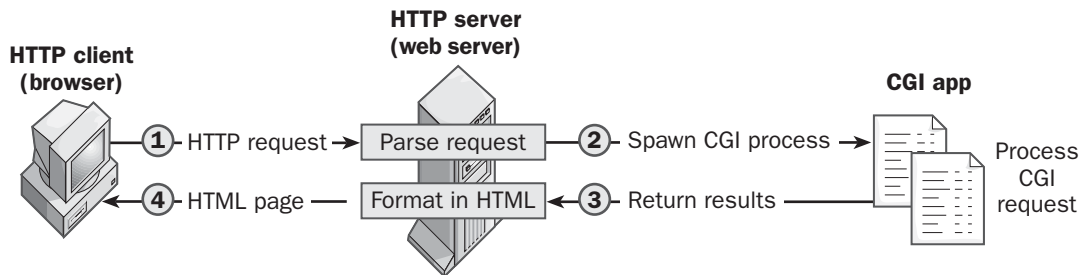

The main disadvantage of CGI is that each request must spawn a new CGI process and that, after the request is satisfied, the process is killed. Thus a Web server experiencing multiple simultaneous requests from clients will spawn multiple copies of the gateway process, each of which consumes memory and processing overhead. The fact that processes are terminated at the end of each request limits CGI to single-step Web applications and requires much ingenuity to handle data across a multi-step user session.

Examples

CGI applications are often used as form handlers for Web forms, and are executed using a <FORM> tag embedded in the form document. When a Web client such as Microsoft Internet Explorer submits a form or otherwise passes information to a Web server using CGI, the Web server receives the information from the client and passes it to the gateway program for processing. The gateway program then returns the result of the processing to the server, which returns it to the Web browser as an HTML page. Here's a simple example:

```
<FORM METHOD=POST ACTION=
"http://www.northwind.microsoft.com/cgi-bin/
results.pl">
```

In this example, the Perl script `results.pl` in the `cgi-bin` directory functions as the form handler for processing the information submitted using the form.

Common Gateway Interface (CGI). How CGI works.

Notes

Although CGI was developed for UNIX-based systems, it is supported by most Web servers, including Microsoft Internet Information Services (IIS). Microsoft Internet Server API (ISAPI) is a set of server extensions for IIS that functions similarly to those of CGI but uses fewer resources. The main difference is that with CGI the system creates a unique process for every CGI request, but ISAPI extensions do not require separate processes. This makes ISAPI applications generally more responsive than CGI applications.

Common Information Model (CIM)

A schema for defining manageable network objects.

Overview

The Common Information Model (CIM) defines a set of schema for describing information collected for network and systems management purposes. CIM was developed by the Distributed Management Task Force (DMTF), formerly named the Desktop Management Task Force, as an extensible, object-oriented schema for managing information collected from computers, networking devices, protocols, and applications.

CIM supports management of two types of objects:

- **Hardware objects:** This includes router interfaces and disks.
- **Software objects:** This includes applications, application components, and services.

Another way of defining the different types of information that can be described by CIM is as follows:

- **Static information:** Examples include the capacity of a hard drive on a desktop computer or the specific applications installed on a server.
- **Dynamic information:** Examples include the current bandwidth being used on a port on a switch or router.

Uses

CIM is similar to the Simple Network Management Protocol (SNMP) and Desktop Management Interface (DMI) standards. However, unlike SNMP and DMI, CIM is able to manage the widest possible range of hardware and software systems. CIM also shows the relationships between the different hardware and software components of an enterprise network more completely, making it easier to troubleshoot complex distributed systems and applications.

CIM information that is collected can be shared between systems on a peer-to-peer basis. This information sharing allows network devices to not only be managed from a centralized management console but also to talk to one another to resolve problems as they arise.

CIM was designed by the DMTF to operate together with their Web-Based Enterprise Management (WBEM) initiative to provide a broad WBEM/CIM framework for managing resources across a network.

Architecture

CIM is based on an object-oriented programming model that allows inheritance to be used to grant subclasses the characteristics of their parent classes. CIM classes have the properties, methods, and associations typical of object classes. CIM supports both physical and logical objects and models these objects for purposes of network management applications. CIM is also extensible and allows vendors to define the features of their products using inherited subclasses. The fact that these subclasses are inherited from standard parent classes ensures that data collected from different vendors' systems will be compatible with the CIM standard.

CIM consists of two parts: a language definition specifying the constructs and methods that can be used to model network and system resources, and a set of schema that describes how specific types of resources will be represented.

CIM supports three kinds of schema:

- **Core schema:** These define general areas of network and system management, and core CIM classes are platform-independent.
- **Common schema:** These define specific areas of management.
- **Extension schema:** These define the management of vendor-specific technologies.

Notes

Microsoft Systems Management Server (SMS) 2 is capable of collecting CIM data from managed systems and exporting this data to other enterprise management applications, such as NetView from Tivoli Systems and Unicenter from Computer Associates.

Common Internet File System (CIFS)

A public version of the Server Message Block (SMB) file-sharing protocol that has been tuned for use over the Internet.

Overview

Common Internet File System (CIFS) is a remote file system access protocol that enables groups of users to collaborate and share documents over the Internet or within corporate intranets. CIFS is an open, cross-platform technology that is based on the native file-sharing protocols of Microsoft Windows platforms. It is supported by other platforms such as UNIX.

CIFS has been viewed as a possible replacement for both the File Transfer Protocol (FTP) and the Network File System (NFS) file system protocols. CIFS supports encrypted passwords and Unicode filenames, and it can be used to mount a remote file system as a directory or drive on the local machine. CIFS also includes features not supported by NFS, including write-ahead and native support for locks. Microsoft Corporation's Distributed file system (Dfs) is covered as part of the CIFS specification.

Microsoft has submitted CIFS to the Internet Engineering Task Force (IETF). CIFS client and server software is available for the Windows 2000 operating system platform.

Common Name Resolution Protocol (CNRP)

A proposed Internet Engineering Task Force (IETF) standard for a protocol to replace Uniform Resource Locators (URLs) with a simpler, more natural scheme for navigating the Web.

Overview

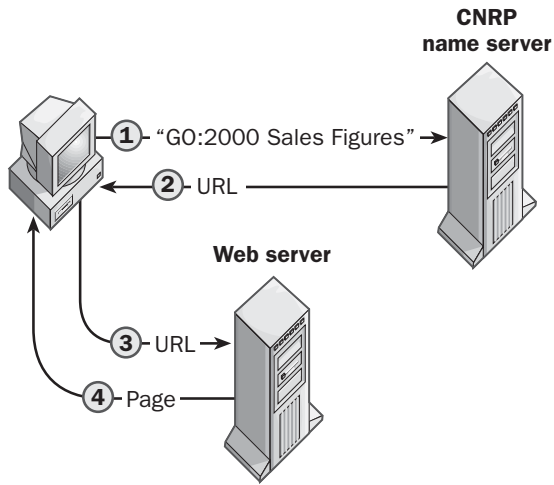

The existing Internet naming systems (domain names and URLs) are not particularly user friendly, as anyone knows who has ever picked up the phone and heard someone ask, "What is the URL for [name of Web page]?" After tediously repeating a long string of characters and slashes, you begin to wish the Internet community could come up with something different.

Enter the proposed Common Name Resolution Protocol (CNRP), an initiative of Network Solutions, AT&T, and other companies. Using CNRP, users could enter the name of a company into their browsers to reach the company home page, then enter a product name to reach the page for a particular product, and enter "2000 Sales Figures" to retrieve a document with these figures. Areas where CNRP might excel include government and public information portals and corporate intranets. Wireless Internet access may also benefit by eliminating the need to enter long, complex URLs on small keypads in order to access specific content on the Internet.

Architecture

CNRP basically runs on top of Hypertext Transfer Protocol (HTTP) as an Extensible Markup Language (XML)-encoded service. A user could enter "Go:2000 Sales Figures" into the browser's address bar, and the browser would encode this request in XML and forward it to a CNRP name server. The name server would then return the URL of the requested page to the browser, which would then request the actual content from where it is located on the Internet or corporate intranet.

C

Common Name Resolution Protocol (CNRP). How the CNRP works.

Current Web browsers do not support CNRP, and until they do, users who want to use this service will have to download a plug-in for their browser to provide this functionality. Network Solutions offers a free, downloadable CNRP plug-in, as do several other vendors. Whether CNRP will become widely used will depend largely on social inertia (most people are used to URLs despite being fed up with them) and on whether CNRP is natively supported by the next release of Microsoft Internet Explorer and other Web browsers.

Common Object Request Broker Architecture (CORBA)

A component architecture that specifies technologies for creating, distributing, and managing component programming objects over a network.

Overview

Common Object Request Broker Architecture (CORBA) was developed by the Object Management Group and its member companies and was designed to provide interoperability between applications in heterogeneous distributed environments.

In a CORBA environment, programs request services through an object request broker (ORB), which allows components of distributed applications to find each other and communicate without knowing where applications are located on the network or what kind of interface they use. ORBs are the middleware that enable client and server programs to establish sessions with each other, independent of their location on the network or their programming interface.

The process of a client invoking a call to an application programming interface (API) on a server object is transparent. The client issues the call, which is intercepted by the ORB. The ORB takes the call and is responsible for locating a server object that is able to implement the request. When it has located such an object, the ORB invokes the object's method and passes it any parameters submitted by the client. The results are then returned to the client. ORBs communicate among themselves using the General Inter-ORB Protocol (GIOP) or the Internet Inter-ORB Protocol (IIOP) so that any ORB can fulfill any client request on the network.

Uses

CORBA is primarily used in the UNIX world as an underlying architecture for developing distributed applications. CORBA is not natively supported by Microsoft Windows, which uses its own distributed object management architecture called Distributed Component Object Model (DCOM). The OMG has indicated, though, that it plans to include support for Microsoft's new C# programming language in CORBA, which should promote interoperability between UNIX applications using CORBA and Web services developed under Microsoft Corporation's new .NET platform.

community

A group of hosts managed by Simple Network Management Protocol (SNMP) running SNMP agents.

Overview

Communities provide a simple way of partitioning and securing a network for SNMP management. SNMP agents and management systems use community names as the mechanism for authenticating SNMP messages. All SNMP agents belonging to the same community share the same community name, which functions as a kind of shared password for those agents so that they can be recognized by the SNMP management program and other agents. SNMP messages sent by SNMP management systems to a specific community are accepted only by hosts configured to belong to that community. If an SNMP agent program receives an SNMP message with a community name that it is not configured to recognize, it typically drops the message and sends a trap message to the SNMP management program indicating that a message was not authenticated on that machine.

Notes

An agent can be a member of one or more communities. By default, all agents belong to the public community. If all community names including public names are removed from an SNMP-managed host, the host will accept all SNMP messages sent to it.

Competitive Local Exchange Carrier (CLEC)

A telco that competes with incumbent telcos under the terms of the Telecommunications Act of 1996.

Overview

Before 1996, the U.S. telecommunications market was dominated by a small group of telcos called Incumbent Local Exchange Carriers (ILECs) or Regional Bell Operating Companies (RBOCs) and a group of long-distance carriers or inter-exchange carriers (IXCs). The Telecommunications Act of 1996 was designed to open things up by allowing new companies to compete with the established ones in both the local and long-distance markets.

Competitive Local Exchange Carriers (CLECs) generally compete with ILECs for provisioning the local loop market, but unlike ILECs, which focus more on residential and large enterprise customers, many CLECs have targeted the small to mid-sized business market that has traditionally been poorly served by ILECs. CLECs generally offer high-speed data services and often focus on specific niche services such as Digital Subscriber Line (DSL)—these are often known instead as DSL providers—but many CLECs also offer a much wider spectrum of services including voice (local and long-distance), high-speed Internet access (using DSL), virtual private networks (VPNs), and business-to-business data links.

CLECs come in many types and range from smaller start-ups that piggyback on ILECs and purchase services wholesale from them for reselling purposes, to larger start-ups building out new fiber from their own switching centers, to large IXC's such as AT&T (which acquired Teleport, a pioneering CLEC) and MCI WorldCom (which bought MFS, another pioneer CLEC) competing in the local telco market.

Like ILECs, CLECs are generally concerned about provisioning buildings, not individual users. However, some CLECs are also getting into the Building Local Exchange Carrier (BLEC) markets by offering to-the-desktop services for building-out wiring and deploying services not just to buildings but also within them.

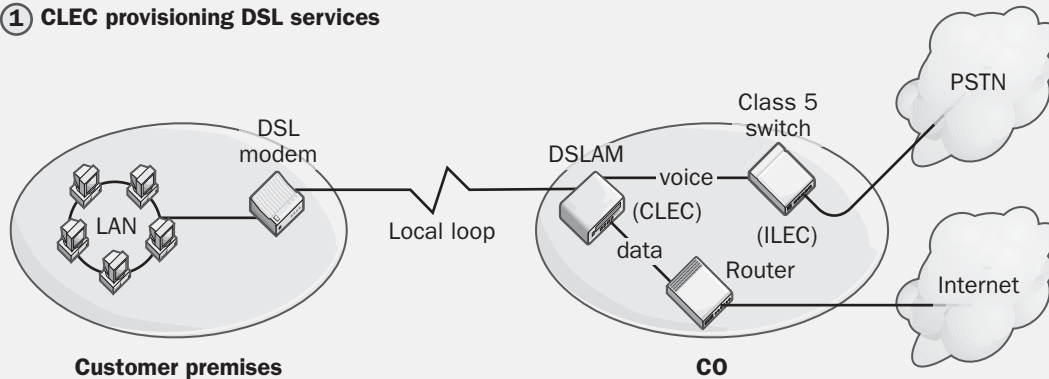

Advantages and Disadvantages

One of the advantages that CLECs have over traditional ILECs is that, instead of competing directly with ILECs by building switching centers, building out wiring to customer premises, and purchasing expensive Class 5 telephone switches to handle all-important voice traffic, they can save implementation costs considerably by colocating their switching equipment at ILEC COs, sharing the existing local loop infrastructure owned by ILECs, and focusing on purchasing more modern, less expensive switching gear dedicated to specific uses such as DSL. Using less expensive and more modern equipment theoretically means the CLEC can offer its services at a discount compared to the ILEC, but CLECs also have to pay the ILECs for the right to use their services, including line provisioning and maintenance, switching interconnects, and colocation services.

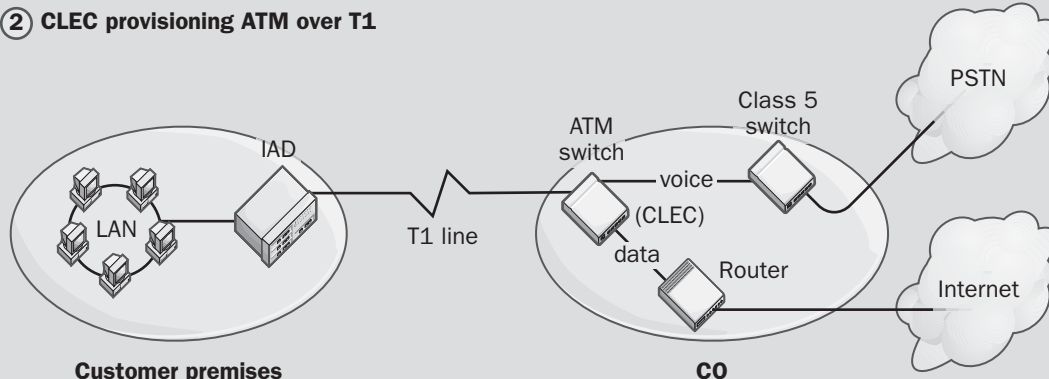

C

① CLEC provisioning DSL services

② CLEC provisioning ATM over T1

Competitive Local Exchange Carrier (CLEC). Two ways CLECs can provision customers with voice and data services.

On the other hand, contracting CLECs to provision telecommunication services for your company instead of ILECs has an element of risk. This is evidenced by the changing nature of the CLEC market, in which some startups have failed and others have been acquired, and by litigation initiated by some CLECs against ILECs. An example is Pronto, a project of mega-bell SBC Communications, which is building out thousands of neighborhood DSL remote terminals to shorten customer DSL connections, thereby improving DSL reliability and data rates. CLECs that want to provide their own DSL services to the same customers have complained to the Federal Communications Commission (FCC) that Pronto cuts them out of the loop because they cannot service Pronto customers using DSLAMs colocated at SBC's COs. Other RBOCs are contemplating similar projects, which could undercut the operations of many CLECs.

Implementation

Because the ILECs own the infrastructure of the last-mile (local loop) wiring serving residential and business markets in the United States, the Telecommunications Act required ILECs to open up use of the local loop to CLECs, allow CLECs to colocate their equipment at the ILEC central offices (COs), and allow CLECs to lease use of the local loop from the ILECs that provision it. CLECs can architect to provision services in many ways, two of which are shown in the diagram.

The top part of the diagram shows a DSL modem at the customer premises that connects the customer's local area network (LAN) over the local loop to a DSL Access Multiplexer (DSLAM) colocated by the CLEC at the CO of the customer's incumbent telco. The CLEC's DSLAM is connected to the ILEC's switching

backbone to provide the customer with voice and data services. Such an arrangement is typical of a CLEC that functions as a DSL provider.

The bottom part shows an Integrated Access Device (IAD) at the customer premises. The IAD converts the Internet Protocol (IP) packets of the customer's Ethernet LAN to Asynchronous Transfer Mode (ATM) cells for transmission over the T1 line to an ATM switch colocated by the CLEC at the ILEC's CO. In this case, the ILEC is responsible for provisioning the T1 for the CLEC and acts as a wholesaler of T1 services toward the ILEC. The CLEC's ATM switch then filters the voice and data traffic from the customer. The voice traffic is routed either to the ILEC's telephone switch or directly to an IXC, while the data traffic is routed to an ISP for Internet access or to an IXC for long-haul wide area network (WAN) connections to branch offices.

Marketplace

The CLEC landscape is constantly changing, but some of the bigger players include Covad Communications Company (www.covad.com), Intermedia Communications (www.intermedia.com), Cogent Communications (www.cogentco.com), and others. Despite these big players and the large number of smaller CLECs on the market, analysts estimate that CLECs currently have less than 10 percent of the local telecom market, with more than 90 percent still in the hands of the incumbent ILEC/RBOCs.

CLECs that provision DSL services typically pay RBOCs about \$15 to \$25 per month to use their local loop connection for deploying such services, the cost of which must be recovered when they resell such services to businesses and consumers, typically at \$40 to \$60 per month. A newer technology called line sharing may lower the cost for CLECs to lease lines from ILECs, and the savings might be passed on to consumers.

Prospects

Times have gotten tough in the telecommunications industry in general at the start of the new millennium. After the dot-com crash of 2000, sources of venture capital for new telecom startups has dried up, leaving some CLECs in financial difficulty (the same difficulties are faced by 3G wireless vendors and other segments of the telecom sector). Although a few CLECs have failed and others have been acquired, there were still about 200 different CLECs

in the marketplace in 2001, with a market capitalization of about \$6 billion.

One aim of the Telecommunications Act of 1996 was to open the doors for cable TV companies and utilities to begin competing with ILECs for residential and business voice and data services. When the act was passed, these companies were slow to build out these services, and a diverse host of CLECs appeared to compete in the residential, office, and metropolitan marketplaces. Now, however, cable companies and utilities are beginning to deploy high-speed data services in large rollouts, and so now many CLECs face competition on two fronts instead of from just the ILECs. Finally, FCC rulings have begun to come down on the side of large carriers, which may squeeze many smaller startups out of the marketplace or lead to their being acquired by big carriers such as AT&T and SBC.

The shakeout in the CLEC market and its uncertain future makes it advisable for businesses to use due diligence in investigating the financial viability of CLECs before deploying mission-critical WAN services just to save costs over similar services offered by RBOCs. Many enterprise network architects believe that leasing reliable services for WAN and Internet access from large RBOCs is more important than saving a few dollars by using CLECs. On the other hand, some e-commerce companies have chosen to go with CLECs because they can typically provision services much faster than traditional RBOCs. CLECs that are building out their own infrastructure (own their own fiber) are probably more likely to succeed in the long term. Enterprise network architects should also consider purchasing redundant services from different carriers to provide fault-tolerance for their WAN connections, but they should realize that as the CLEC market consolidates, their options may narrow.

C

complete trust model

A domain model in Microsoft Windows NT in which every domain trusts every other domain with two-way trusts.

Complete trust model. Shown for Windows NT.

Overview

The complete trust model is rarely implemented in Windows NT-based networks unless the motivation for using Windows NT is being driven from the bottom up. For example, if a number of individual departments start implementing domains, the company might soon find itself implementing the complete trust model in order to make administration of these domains more efficient. This model also might be used in a situation in which two companies using Windows NT merge into a single company. Because of the large number of trusts in a complete trust model, there are additional security concerns about who is able to administer what. The following table outlines the pros and cons of using this domain model.

Advantages and Disadvantages of Using the Complete Trust Model

<i>Advantages</i>	<i>Disadvantages</i>
Scalable to any number of user accounts.	Complex to set up and administer.
Suitable for merging companies or organizations with no central MIS department.	Multiple local groups must be created in each resource domain.

Notes

When you upgrade a Windows NT network based on the complete trust model to a Windows 2000 or Windows .NET Server network, you can maintain the relative independence of each domain by migrating each domain to be the root domain of a domain tree. Each domain tree would have a single domain, namely the root domain. Two-way transitive trusts can then be established between the trees to form a domain forest.

Component Load Balancing (CLB)

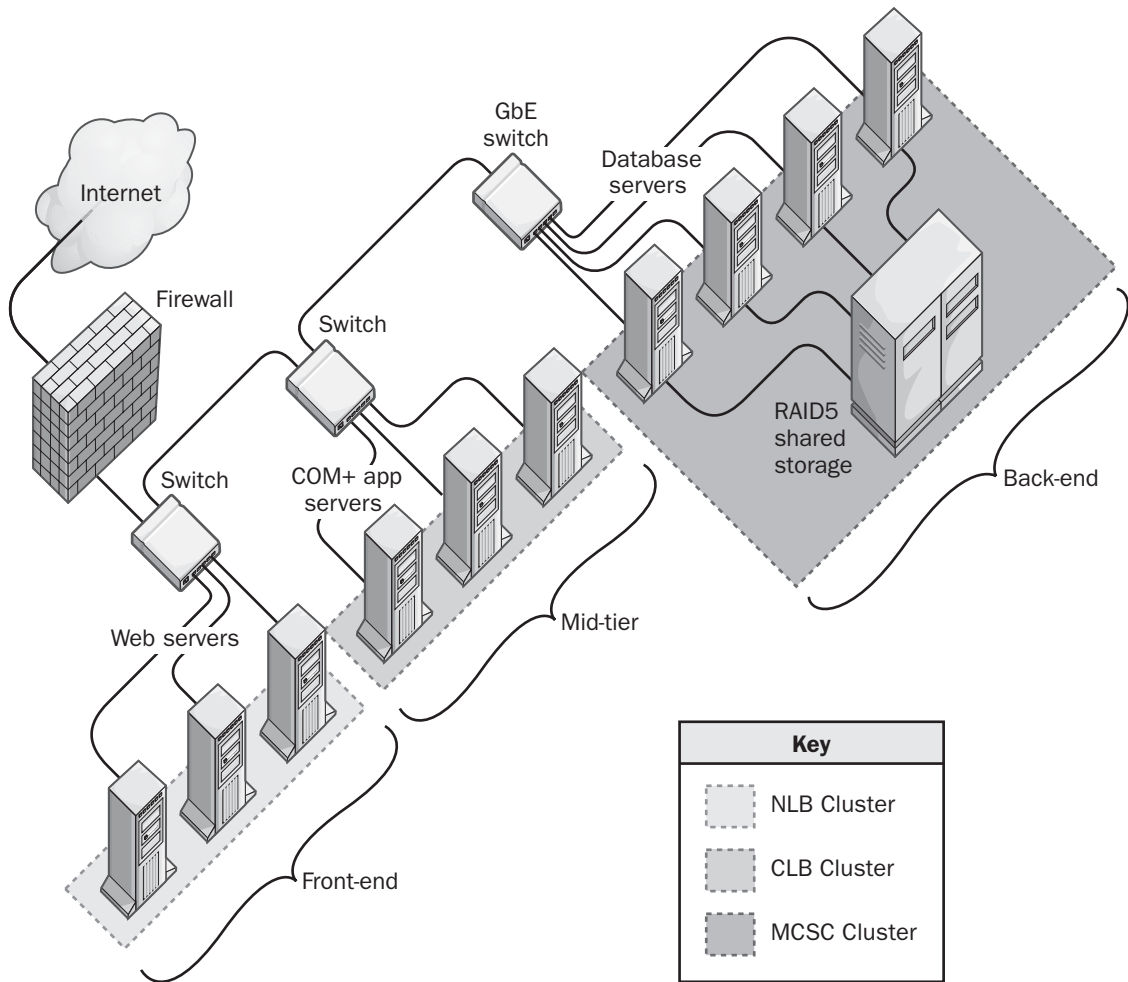

A Microsoft clustering technology supported by Microsoft Windows 2000 and Windows .NET Server Server and provided by Microsoft Application Center 2000.

Overview

Component Load Balancing (CLB) is a Microsoft clustering solution that is designed to increase the availability and reliability of distributed applications developed using Microsoft COM+ technologies. A CLB cluster consists of a group of up to 16 nodes (servers) running a distributed COM+ application whose components are distributed across the cluster. A CLB cluster is connected together by a network and is managed by Application Center 2000. When one node in a CLB cluster fails, its workload is distributed to the remaining nodes and the COM+ application keeps running.

Implementation

CLB is usually used in conjunction with other forms of clustering such as Network Load Balancing (NLB) and Microsoft Cluster Services (MSCS) for Microsoft Windows 2000 and Windows .NET Server Enterprise Server edition. This scenario is often used for farms of Web servers running mission-critical Web applications. Typically, NLB is used to handle load balancing of Web servers at the front-end, while CLB load balances COM+ application logic in the middle tier and MSCS provides clustering for back-end database servers. Application Center 2000 is then used to manage the CLB middle tier of the Web farm.

Component Load Balancing (CLB). Using CLB to provide high reliability and availability for distributed COM+ applications.

To distribute the load across the nodes of the CLB cluster, CLB uses round-robin techniques and polling algorithms based on server response time. Because CLB uses frequent polling, be sure to implement your CLB cluster on a fast network (100 megabits per second [Mbps] or faster).

Component Object Model (COM)

An object-based programming architecture developed by Microsoft Corporation that allows applications to be built from binary software components.

Overview

Component Object Model (COM) is both a set of specifications for building application components and a group of underlying services for supporting these components. COM defines a standard method for building components and specifies what these components will

C

look like at the binary level. Because it is a binary standard, COM is language-neutral and COM components can be written using a variety of programming languages including C++, Visual Basic, Java, COBOL, SmallTalk, and other languages. COM also has the following features:

- Support for object-oriented programming features including encapsulation, inheritance, and polymorphism.
- Location transparency, which allows COM components to be moved from one system to another.
- Portability, which lets you port COM applications to other operating system platforms.
- Code reuse, the result of encapsulation of COM functionality and a way to speed up application development.
- Loose coupling, which lets you replace components with new ones that have similar interfaces for accessing them.
- Stable version transitioning, which lets you upgrade some components within an application without breaking the application.

History

Microsoft released an earlier technology, Object Linking and Embedding (OLE), in 1991. OLE enabled functionality from one application to be embedded into another application. For example, a Microsoft Excel spreadsheet could be embedded into a Microsoft Word document and still maintain its spreadsheet functionality. OLE used an underlying technology called Dynamic Data Exchange (DDE) that was complicated in its operation.

In 1995, OLE 2 was released, which replaced DDE with COM as an underlying architecture for OLE. It was soon realized that COM had more uses than embedding one document within another, and COM became the fundamental technology while OLE withdrew to the background. COM has continued to evolve, and its present version is called COM+, which is discussed in a separate article in this chapter.

Implementation

The basic unit of COM is the COM component object, a binary programming object that complies with the COM standards. COM objects can be implemented as either executable (.exe) files or dynamic-link libraries (DLLs) and can function in one of two roles: COM servers (providers) and COM clients (consumers). COM servers and clients interact with each other by using COM interfaces.

A COM interface is a set of methods by which a COM object exposes its functionality to other COM objects. COM interfaces allow COM objects to invoke one another through the methods and properties residing in these interfaces. COM interfaces consist of groups of related functions implemented by the COM class. An interface is basically a table of pointers to functions that are implemented by the object. The table represents the interface, and the functions to which the table points represent the methods of that interface. COM objects can expose multiple interfaces. Each interface has its own unique interface ID (IID), and COM interfaces begin with the letter "I." For example, IUnknown is an important COM interface that must be included in every COM object. IUnknown provides reference counting and interface querying mechanisms and allows navigation to all other interfaces exposed by COM objects.

When COM-based applications are written, COM components are identified by globally unique identifiers (GUIDs), a 16-byte (128-bit) alphanumeric string that is uniquely generated using the current data and time and other information. COM component objects must be registered in order for location transparency to work. You can manually register a COM component object using Regsrv32.exe and other tools.

COM also includes a set of COM services implemented as Win32 library routines (DLLs). These DLLs are used to create new instances of COM components, find and keep track of the location of COM component objects, and perform remote procedure calls (RPCs) for communicating between component objects.

Notes

An alternate component object technology found primarily in the UNIX world is Common Object Request Broker Architecture (CORBA).

computer account

An account in the Active Directory directory service of Microsoft Windows 2000 and Windows .NET Server that signifies that a particular computer is a part of a Windows 2000 or Windows .NET Server domain.

Overview

Windows 2000 and Windows .NET Server domain controllers can store three types of accounts: user accounts, group accounts, and computer accounts. Windows 2000 and Windows .NET Server use computer accounts to determine whether a particular system that a user is employing to attempt to log on to the network is part of the domain. When the NetLogon service running on a client computer connects to the NetLogon service on a domain controller in order to authenticate a user, the NetLogon services challenge each other to determine whether they both have valid computer accounts. This allows a secure communication channel to be established for logon purposes.

In order for a Windows 2000, Windows XP, or Windows .NET Server machine to join a domain,

the machine must have a computer account created for it in Active Directory. There are two ways to create this account:

- Use Active Directory Users and Computers in Windows 2000 and Windows .NET Server to create a computer account for the machine, and then have the machine join the domain.
- Use an administrator account to create a computer account while installing Windows 2000, Windows XP, or Windows .NET Server on the machine.

Notes

Machines running Windows 95, Windows 98, and Windows Millennium Edition (Me) can participate in domain authentication, but they do not have computer accounts in Active Directory. This is why the logon box for a Windows 95 or Windows 98 machine has a hard-coded domain name and can log on to only one domain.

If you reinstall Windows 2000 on a machine, you must delete the old computer account and create a new computer account, even if the machine has the same name as before.

Computer Browser service

In Microsoft Windows 2000, Windows XP, or Windows .NET Server, a service responsible for enabling the browsing of network resources using Network Neighborhood and Windows Explorer.

Overview

The Computer Browser service simplifies the user task of locating and accessing network resources by eliminating the need for users to remember Universal Naming Convention (UNC) paths or other network syntax and by eliminating the need for all computers on the network to maintain their own list of all available network resources.

The Computer Browser service maintains a distributed series of lists called browse lists that contain information about shared resources available on the network.

Different computers on the network have different roles. These computers include the following:

- Domain master browser:** Collects and maintains the master browse list for the domain, and synchronizes this list with other domain master browsers in different domains. In a Windows NT network, the domain master browser must be the Primary Domain Controller (PDC).
- Master browser:** Collects and maintains the master browse list for the domain and distributes this list to backup browsers in the domain. This can be a computer running Windows 2000, Windows XP, Windows .NET Server, Windows NT, Windows 95, Windows 98, or Windows for Workgroups.
- Backup browser:** Maintains copies of the browse list received from the master browsers and distributes this list to any network client requesting a network resource. This can be a computer running Windows 2000, Windows XP, Windows .NET Server, Windows NT, Windows 95, Windows 98, or Windows for Workgroups.
- Potential browser:** Any computer on the network configured so that it can assume the role of a master browser or backup browser if required. This can be a computer running Windows 2000, Windows XP, Windows .NET Server, Windows NT, Windows 95, Windows 98, or Windows for Workgroups.
- Nonbrowser:** Any computer that cannot be a browser but can share resources with the network.

Computer Browser service. How the Computer Browser service works.

When a client tries to access a shared resource on the network, such as a shared folder on a file server, it first contacts the master browser for a list of backup browsers. Then it contacts a backup browser for a copy of the browse list. When the client has the browse list, it contacts the file server for a list of shares, and then connects to the desired share.

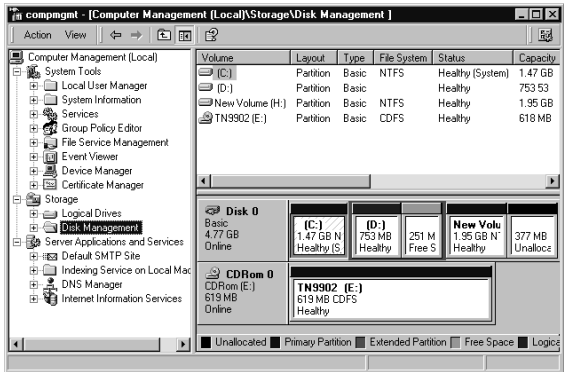

Notes

The Workstation service and Server service must be started for the Computer Browser service to function.

Computer Management

A Microsoft Windows 2000, Windows XP, and Windows .NET Server management console that provides a single integrated desktop tool for managing local and remote machines.

Computer Management. A typical Computer Management console.

Overview

Computer Management combines a number of administrative utilities from Windows NT with additional Windows 2000, Windows XP, and Windows .NET Server tools to provide an easy way of viewing and managing properties of any computer running Windows 2000, Windows XP, or Windows .NET Server on the network. Using Computer Management, an administrator can perform the following actions on local and remote machines:

- Create and manage shares
- Display a list of connected users

- Manage services such as Dynamic Host Configuration Protocol (DHCP) and Domain Name System (DNS)
- Start and stop system services
- Configure properties of storage devices
- Monitor system events and application errors
- Display device settings and add new device drivers

To use Computer Management for modifying administrative settings, you must be a member of the Administrators group.

computer name

For computers running Microsoft Windows, a name that identifies a computer on the network.

Overview

Computer names can be up to 15 characters in length. In Windows NT, Windows 95, and Windows 98, you specify a computer's name using the Network utility in Control Panel. (In Windows 2000, Windows XP, and Windows .NET Server, use the Network Identification tab of the System utility in Control Panel.) The computer must be restarted if its name is changed. This name is used by services that perform NetBIOS name resolution on the network, such as the Windows Internet Name Service (WINS). Computer names provide a friendly way of accessing network resources without having to remember complex numerical addresses such as IP addresses.

A hidden 16th character is appended to the computer name to form the NetBIOS name for NetBIOS-aware networking services on the machine. Each NetBIOS-aware service has a different NetBIOS name, some of which are based on the name of the computer and others of which are based on the name of the domain in which the computer resides.

Notes

Give friendly names, derived from some common source such as *A Midsummer Night's Dream*, to groups of computers offering related services. For example, you could call your servers Puck, Oberon, and Titania. This makes it easy to remember that these computers all belong to the same group.

computer-telephony integration (CTI)

A general term describing the integration of computer and telephone technologies.

Overview

By joining computer systems with switched telephone services, users can access advanced functions such as automatic incoming call routing, call display, and power dialing. For example, a computer can use computer-telephony integration (CTI) to issue commands to a telephone switch to control call routing of calls.

CTI applications generally fall into one of two categories:

- **Call-control applications:** Allow computers to dial numbers, establish conference calls, and other functions. The computer essentially replaces the touch-tone telephone keypad.
- **Media-processing applications:** Deal with more complex issues, such as voice recognition, speech synthesis, and converting fax messages to e-mail. These applications pursue the goal of completely integrated unified messaging in which voice, fax, e-mail, and video conferencing features are combined.

CTI is made possible on Microsoft Windows platforms by operating system application programming interfaces (APIs) such as Microsoft Corporation's Telephony Application Programming Interface (TAPI). The range of products and technologies that support CTI continues to evolve. Cross-platform, vendor-neutral standards have not yet been established.

Computing Technology Industry Association (CompTIA)

A computer industry trade association formed in 1982.

Overview

The Computing Technology Industry Association (CompTIA) currently has more than 7500 members. CompTIA membership includes resellers, value-added resellers (VARs), distributors, manufacturers, and training companies in the United States and Canada. The goals of CompTIA are to foster professional competence and business ethics among its members and

throughout the computer industry. CompTIA provides its members with educational opportunities, a professional network, and a forum for the development of ethical, professional, and business standards in the computing industry. A number of committees meet to consider issues such as software licensing and electronic warranty forms.

COMTI

Stands for COM Transaction Integrator, a component of Microsoft SNA Server version 4 that provides client applications with access to two popular mainframe transaction processing (TP) environments, Customer Information Control System (CICS) and Information Management System (IMS).

See: COM Transaction Integrator (COMTI)

COM Transaction Integrator (COMTI)

A component of Microsoft SNA Server version 4 that provides client applications with access to two popular mainframe transaction processing (TP) environments, Customer Information Control System (CICS) and Information Management System (IMS).

Overview

COM Transaction Integrator (COMTI) works in conjunction with Microsoft Transaction Server (MTS), making CICS and IMS programs appear as MTS components that can be used with other MTS components to build distributed applications. COMTI includes both a Microsoft Windows NT Server run-time environment and a development tool called Component Builder, which can import mainframe COBOL code and automatically generate an object compatible with MTS. This lets developers program in the visual, object-oriented environments they are accustomed to, allowing them access to host transactions without needing to learn the intricacies of Systems Network Architecture (SNA).

See Also: SNA Server; Systems Network Architecture (SNA)

concurrency

A term referring to the simultaneous access to a network resource by more than one client.

Overview

Concurrency is an important issue in the licensing of a server operating system or application. For example, the Per Server licensing mode for Microsoft Windows NT Server is based on concurrency. If you purchase 10 client access licenses (CALs) for your Windows NT Server, a maximum of 10 concurrent connections can legally be formed with that server for accessing network resources.

Notes

Some products, such as Microsoft Outlook 98, do not support concurrent access. In other words, you cannot install a central copy of Outlook 98 on a server and have thin clients run this program from the centralized location. Instead, you must install one copy of Outlook 98 on each client that needs to run it.

connected network (CN)

In Microsoft Message Queue (MSMQ) Server terminology, a name for a collection of computers in which any two computers can directly communicate.

Overview

Computers in the same connected network must be running the same network protocol. A connected network (CN) is essentially a label describing how MSMQ servers are related in an enterprise. CNs are logical groupings of computers that can communicate directly using MSMQ messages. When you install an MSMQ server, you specify a connected network for each network address on the server.

When you specify connected networks for your MSMQ enterprise, it is a good idea to use meaningful labels so that administrators can easily select a connected network from a list when they need to override the default connected network settings.

connection

A link between two computers for the purpose of exchanging information.

Overview

An example would be a Microsoft Windows NT Workstation, Windows 95, or Windows 98 client computer accessing a shared folder or printer on a Windows 2000 server. The term *connection* is also used to describe the establishment of communication over a WAN link, as in using a dial-up connection over a modem.

When a client computer tries to connect to a server, the success or failure of the attempt can depend upon whether

- The server has shared the resource that the client wants to connect to
- The client has been properly authenticated or has permission to access the resource
- The client is properly licensed to connect to the server, and free licenses are available

connectionless protocol

Any transport layer protocol that relies on broadcast packets instead of directed packets.

Overview

Connectionless protocols can only offer “best-effort” delivery and cannot guarantee that packets will arrive in the correct order or even at all. Connectionless protocols cannot guarantee delivery of packets. Instead, reliability of packets is handled by the application itself or some higher layer of the protocol stack.

An example of a connectionless protocol is the User Datagram Protocol (UDP), which is part of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite. UDP provides connectionless services for delivering small packets of information commonly called datagrams. Another connectionless transport layer protocol is the Appletalk Transaction Protocol (ATP), part of the AppleTalk suite of protocols.

Notes

The term *connectionless* is also used to describe any delivery mechanism where complete addressing information (the address of the source and the address of the destination) is included in every packet. Packets are

then placed on the network and are delivered to their destination independently, sometimes taking different routes and arriving in a mixed-up order that needs to be sorted out using packet numbers.

In this more general context, we can also examine protocols at other layers such as the network layer and data link layer. Most local area network (LAN) protocols at these layers are connectionless. For example, at the network layer we have IP, Internetwork Packet Exchange (IPX), Datagram Delivery Protocol (DDP), which is part of the legacy AppleTalk protocol suite, and DECnet Routing Protocol (DRP), which is part of the legacy DECnet protocol suite, all connectionless. At the datalink layer we have Ethernet, Token Ring, Fiber Distributed Data Interface (FDDI), and others, again all connectionless. An example of a data-link layer protocol that is connection-oriented instead of connectionless is Asynchronous Transfer Mode (ATM).

Connection Manager Administration Kit (CMAK)

A wizard-based tool for creating custom connectivity solutions, and a component of Internet Connection Services for Microsoft Remote Access Service (RAS).

Overview

The Connection Manager Administration Kit (CMAK) is used to customize the Microsoft Connection Manager (CM) client component. Internet service providers (ISPs) can use this tool to customize dial-up installation packages for their customers. Customization features include

- Animated logon screen, which can include a custom logo
- Desktop icons
- The language the dialer displays to the customer
- Support numbers and help files
- Various connect actions that the dialer performs when dialing, such as shutting down applications or downloading files

connection-oriented protocol

Any transport layer protocol that establishes a connection first in order to reliably send packets over the network.

Overview

Connection-oriented protocols guarantee delivery of packets by making use of acknowledgments and retransmission of data. Connection-oriented protocols are used primarily for reliable delivery of large packets of data, as opposed to the unreliable connectionless protocols that are used to deliver small datagrams.

An example of a connection-oriented protocol is TCP, which is part of the Transmission Control Protocol/Internet Protocol (TCP/IP) protocol suite. The TCP protocol uses a TCP three-way handshake to establish a connection between two hosts on a network. During session establishment, the hosts negotiate the TCP window size, segment size, and other information needed to ensure reliable and efficient communication. A TCP connection is terminated using a similar handshake procedure. Another example of a connection-oriented transport layer protocol is Sequenced Packet Exchange (SPX), part of the NetWare suite of protocols. The legacy network service provider (NSP) protocol of the DECnet suite of protocols is also a connection-oriented transport layer protocol.

Notes

At lower Open Systems Interconnection (OSI) levels such as the network layer and data link layer, most local area network (LAN) protocols are connectionless instead of connection-oriented. Asynchronous Transfer Mode (ATM) is an exception and is connection-oriented. In ATM a virtual circuit (data pathway) is first established prior to sending any data. Instead of addressing data packets (actually cells) with source and destination addresses as in a connectionless protocol, ATM assigns the circuit number to the cells to ensure they reach their destination. Because circuit numbers are much smaller than network addresses, connectionless protocols such as ATM have less overhead than connection-oriented protocols such as IP or Ethernet.

connection pooling

A technique for optimizing Active Server Pages (ASP) applications running on Microsoft Internet Information Server (IIS) version 4 and Internet Information Services (IIS).

Overview

Connection pooling allows more efficient implementation when connecting ASP front-end applications to a back-end database. Connection pooling involves the pooling of open database connectivity (ODBC) connections to reduce the frequency at which ODBC connections need to be opened and closed on heavily accessed servers. Connection pooling improves ASP performance for ODBC-enabled Web applications and provides a graceful way to manage connection timeouts.

To use ODBC connection pooling on IIS, perform the following steps:

- 1 Configure the database driver using ODBC in Control Panel.
- 2 Enable connection pooling in the Microsoft Windows NT registry.
- 3 Open individual connections in your Microsoft ActiveX Data Objects (ADO) code right before data access is needed for an ASP page and release connections as soon as the data has been accessed.

When connection pooling is enabled, the ODBC driver will check the connection pool for idle connections it can reuse before creating a new connection in response to an ODBC request. When connections are released, they are returned to the connection pool instead of being closed.

Notes

You can control the amount of time an idle connection remains in the pool using the CPTimeout registry setting, which has a default setting of 60 seconds.

connectivity server

A computer running Microsoft Exchange Server that is dedicated for routing messages to other sites and foreign mail systems using Exchange connectors.

Overview

Large companies often require servers that are dedicated to message routing because of the high volume of message traffic they experience. In a typical high-volume site configuration, one server might be optimized as a home server for users' mailboxes, another server for dedicated public-folder replica hosting, and a third for providing dedicated messaging connectivity with other sites and foreign messaging systems. A connectivity server can have one or more connectors installed on it to provide connectivity with Exchange sites, Simple Mail Transfer Protocol (SMTP) hosts, X.400 messaging systems, or Microsoft Mail postoffices. The more connectors you have on a server, the greater its hardware requirements become.

Notes

On Exchange 5.5 systems, run the Performance Optimizer wizard after you have installed your connectors on the Exchange server. This will allow your server to take maximum advantage of its particular hardware configuration.

connector (device)

A device that terminates a segment of cabling or provides a point of entry for networking devices such as computers, hubs, and routers.

Overview

Connectors can be distinguished according to their physical appearance and mating properties, such as jacks and plugs (male connectors) or sockets and ports (female connectors). They can also be distinguished by their different pinning configurations, such as DB9 and DB15 connectors, which have 9 and 15 pins, respectively. In addition, connectors are distinguished by the kind of electrical interfaces they support. Examples of different types of connectors include

- Connectors for serial interfaces, such as RS-232 and V.35
- Ethernet connectors, such as RJ-45 and bayonet Neill-Concelman (BNC) connectors
- Fiber-optic cabling connectors, such as SC and ST connectors

C

BNC	BNC		BNC-T		
DB	DB9	DB15	DB25	DB37	DB50
V series	V.35		V.24		M/50
Modular	RJ-11 (4-wire)	RJ-12 (6-wire)	R-J-45 (8-wire)		
Centronics	Centronics (36-pin)			Centronics (parallel)	
Fiber-optic	SMA 905	SMA 906	ST	SC	
HD	HD 15	HD 15-pin 1	HD 15-pin video	HDI 30-pin	
SCSI	SCSI-1 (Telco or Centronics 50)		SCSI-2 (Mini D50 or Micro DB50)		SCSI-3 (Micro DB68)

Connector (device). Common networking and telecommunications connectors.

A single connector may be used for a variety of purposes and different interfaces. For example, the DB-60 connector supports any of the following interfaces: V.35, X.21, EIA-530, EIA/TIA-232, and EIA/TIA-449. So you cannot always tell from the appearance of a connector what its function is—it depends on the interface it implements.

There are literally dozens of types of connectors used in networking, and the networking professional needs to be familiar with many of them. The illustration shows some of the common connector types used in different aspects of networking and telecommunications. Many of these connectors are discussed in separate articles elsewhere in this book.

Connector for Lotus cc:Mail

A component of Microsoft Exchange Server 5.5 that enables message transfer and directory synchronization between Exchange Server and Lotus cc:Mail systems.

Overview

Lotus cc:Mail uses a shared-file messaging architecture similar to that of Microsoft Mail. The Connector for Lotus cc:Mail is implemented as a Microsoft Windows NT service on Exchange Server and supports the following functions:

- Message transfer between Exchange Server and cc:Mail messaging systems
- Synchronization of directory information between Exchange Server and cc:Mail servers

Only one Connector for Lotus cc:Mail can be installed on a given computer running Exchange Server, and that connector can connect to only one cc:Mail postoffice. However, multiple computers running Exchange Server can each have a cc:Mail connector installed in order to connect to multiple postoffices throughout a cc:Mail messaging system. The Lotus cc:Mail programs export.exe and import.exe must be installed on the computer running Exchange Server for connectivity to be established.

The Connector for Lotus cc:Mail can be used to provide connectivity with database versions 6 or 8 cc:Mail postoffices.

Connector for Lotus Notes

A component of Microsoft Exchange Server 5.5 that enables message transfers and directory synchronization between Exchange Server and Lotus Notes systems.

Overview

The Connector for Lotus Notes allows either single or multiple Lotus Notes servers to be accessed from a single machine running Exchange Server. The Connector for Lotus Notes is implemented as a Microsoft Windows NT service on Exchange Server and supports

- Message transfer between Exchange Server and Lotus Notes
- Synchronization of directory information between Exchange Server and Lotus Notes

The Connector for Lotus Notes also converts message content to Rich Text Format (RTF) and converts Object Linking and Embedding (OLE) objects on Exchange Server to Lotus Doclinks objects.

The Connector for Lotus Notes supports Lotus Notes 3.x and Lotus Notes/Domino 4.x.

Notes

Be sure to install the Lotus Notes client on the computer running Exchange Server prior to attempting to install the Connector for Lotus Notes on the machine. The connector needs this client to log on to the Lotus Notes mail server. If you have trouble establishing connectivity, check that the connector has a valid Lotus Notes ID and that this ID has the appropriate permissions needed to access the databases on the machine running Lotus Notes.

connector (Microsoft Exchange)

A component of Microsoft Exchange Server 5.5 used to connect Exchange sites or to connect an Exchange organization to foreign mail systems.

Overview

Connectors are components of Exchange that can be used to route messages over a messaging system.

C

Connectors are implemented on Exchange as Microsoft Windows NT services and can be stopped and started using the Services utility in Control Panel.

Various types of connectors can be installed on Exchange, including the following:

- **Site Connector:** Used for establishing high-speed messaging links between different sites in an Exchange organization
- **X.400 Connector:** Used for establishing connectivity with a foreign X.400 messaging system such as those found in different parts of Europe
- **Dynamic RAS Connector:** Used for establishing dial-up connectivity between sites in an Exchange organization
- **Internet Mail Service:** Used for establishing connectivity with the Internet's Simple Mail Transfer Protocol (SMTP) messaging system
- **Microsoft Mail Connector:** Used for establishing messaging connectivity with legacy Microsoft Mail networks
- **Connector for Lotus cc:Mail:** Used for establishing connectivity with a foreign cc:Mail system
- **Connector for Lotus Notes:** Used for establishing connectivity with a Lotus Notes network

Consumer DSL (CDSL)

A broadband transmission technology based on Digital Subscriber Line (DSL) technologies.

Overview

Consumer DSL (CDSL) was developed by Rockwell and is a slower technology than the more common DSL variant called Asymmetric Digital Subscriber Line (ADSL). CDSL provides data rates of about 1 megabit per second (Mbps) downstream (about 128 kilobits per second [Kbps] upstream) to the customer premises over standard Plain Old Telephone Service (POTS) local loop wiring.

However, CDSL has the advantage of not requiring installation of a splitter at the customer premises. CDSL can operate only at distances of up to 18,000 feet (5500 meters) from the telco's central office (CO).

See Also: *Digital Subscriber Line (DSL)*

container (Active Directory)

In Microsoft Windows 2000 and Windows .NET Server, an object in Active Directory directory service that can contain other objects.

Overview

Examples of containers include organizational units (OUs), domains, and local networks. Domains are the core containers for organizing the structure of Active Directory. The other kinds of objects in Active Directory are leaf objects, which cannot contain other objects.

Objects created in a container inherit the discretionary access control list (DACL) of the container itself. In other words, a child object obtains its permissions from its parent object by inheritance.

Notes

Groups are not containers; they are security principals.

See Also: *Active Directory*

container (Microsoft Management Console)

In Microsoft Management Console (MMC), any node in a console tree to which other nodes can be added.

Overview

The usual icon for a container in MMC is the folder icon. The highest-level container in a console is the console root node. Beneath this node in the hierarchy are the top-level nodes for individual snap-ins that have been installed. Administrators who are creating new MMC consoles can create additional containers (folders) for organizing their console trees as desired.

See Also: *Microsoft Management Console (MMC)*

container (NTFS)

In NTFS file system (NTFS), a file system object (such as a directory) that can contain other objects (such as files).

Overview

Objects created in a container inherit the access control list (ACL) of the container itself. In other words, a child object obtains its permissions from its parent object by inheritance. For example, if a directory on an NTFS volume has read permission assigned to the Everyone group, any new file that you create or save in the directory will inherit the same permission. Using containers therefore simplifies the assignment of permissions to objects in the file system.

Content Advisor

A feature of Microsoft Internet Explorer that allows you to control user access to Web sites based on the content ratings of the sites.

Overview

The Internet provides individuals with access to a wide variety of information, but some of this information might be unsuitable for certain viewers. For example, parents are often concerned about their children being exposed to violent or sexually explicit material on the Internet.

Content Advisor lets you control the kind of Internet content that can be accessed using Internet Explorer. This is a useful feature in corporate networks that have high-speed connectivity to the Internet because it can be used to discourage improper use of Web browsers on employee machines, thus helping to implement a company's acceptable use policy for the Internet. With Content Advisor, you can specify ratings settings to indicate acceptable levels of content to view with regard to sex, nudity, violence, and offensive language, and you can password-protect these settings.

Notes

Content Advisor functions properly only with Web sites that are rated.

Content Analyzer

A tool included with Microsoft Site Server and Microsoft Site Server Express that lets Web server administrators perform content analysis and link management of Web sites.

Overview

Content Analyzer can visually display the structure and integrity of a site in the form of a diagram called a Web map. Web maps allow administrators to visually examine a site's structure and quickly identify problems, such as loops and broken links. Web maps display various Web content items using different icons and can use a variety of colors to convey different kinds of information. You can also use Content Analyzer to search Web maps for various kinds of information using predefined Quick Searches. When you find an item of interest on a Web map, you can open your Web page editing tool directly from the Web map. You can also export Web map information into a database or spreadsheet file for further analysis.

Content Analyzer can also generate predefined site reports you can use to identify broken links and analyze the structure of Web sites. These site reports can be generated in Hypertext Markup Language (HTML) format for easy reading and evaluation and can identify changes to the content of a site, broken links, and other information.

content caching

A feature of a proxy server such as Microsoft Proxy Server.

Overview

Content caching allows a proxy server to cache the results of a client request. The next time a client requests the same content, it is retrieved from the cache to improve performance. Content remains in the cache for a predetermined period of time, or until the cache becomes full and old content is moved to allow new content to be cached.

Microsoft Proxy Server makes use of distributed caching, which lets content caching take place closer to users and allows caching activity to be load-balanced across several Proxy Servers for scalability and fault tolerance. For example, within corporate intranets, caching can be moved toward the branch office and workgroup levels of the organization. For Internet service providers (ISPs), caching can be moved toward

C

regional points of presence (POPs). Distributed caching is particularly effective for solving network bandwidth problems associated with Internet push technologies.

Microsoft Proxy Server's distributed caching can be implemented in two ways:

- **Array-based caching:** In this approach, an array or group of proxy servers works together and is administered as a single, logical entity. A cache array provides load balancing, fault tolerance, scalability, and ease of administration. Cache arrays can provide a higher cache hit rate than an individual proxy server because of the larger size of the virtual cache.
- **Hierarchical caching:** In this approach, you arrange proxy servers in a hierarchy by branch office or department. Requests from clients are then forwarded up the hierarchy until the requested object is found in a proxy server's cache.

content delivery network (CDN)

A method for efficiently pushing out content over the Internet to users.

Overview

The idea of content delivery networks originated as the next evolutionary step up from caching of Web content on the Internet. Like caching, the idea of CDN is to deliver content to users over the Internet as efficiently and quickly as possible. CDN takes caching a step further by actively pushing content out rather than passively caching frequently-requested content. A company that builds and operates a CDN is sometimes called a Content Delivery Provider (CDP).

Akamai Technologies developed the first CDN solution to efficiently deliver streaming media content over the Internet. Akamai accomplished this through alliances with regional Internet service providers (ISPs) for hosting their caching servers around the globe and setting up their own advanced Web hosting centers. Akamai then used forward-proxy caching servers at their

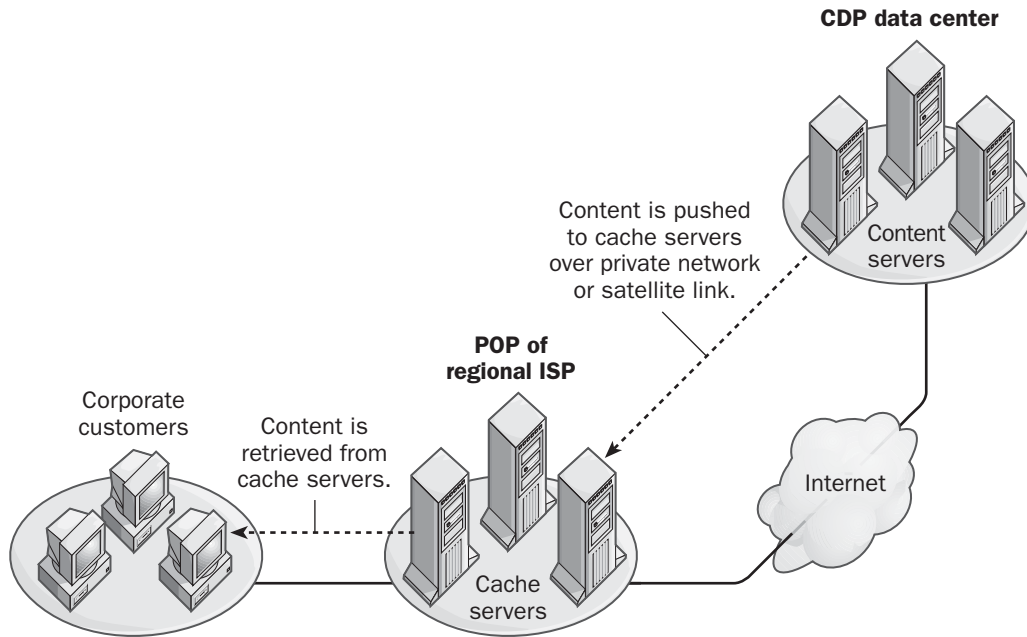

hosting centers to push content out to caching servers at the edges of the Internet, allowing users around the globe to access streaming media presentations from nearby caching servers instead of from centralized streaming media servers many network hops away. The result was a system with better performance than existing implementations of streaming media.

CDNs are now used not just for streaming media but for supporting a wide variety of different kinds of content delivered over the Internet including static and dynamic Web content, video-on-demand, and other services.

Implementation

There are many ways to implement a CDN, and the technology continues to evolve rapidly. A simple example would be a CDP that hosts content for a company on Web and media servers in its data center and then uses a private network to push this content out to caching servers colocated at points of presence (POPs) of regional ISPs located near the company's customers. The private network could be a satellite link, leased lines, private backbone networks (such as those owned by AT&T Wireless), or a leased portion of Internet backbone bandwidth (usually an expensive solution). Private peering arrangements between ISPs and the CDP enable the CDN to work. Personalization servers keep track of user personalization data for customers in different regions.

The resulting CDN can be envisioned as a "content island" within the ocean representing the Internet—only subscribers on this island can make use of the CDN to improve access to hosted content. With many CDNs in existence around the globe and run by different CDPs, interoperability between them becomes an issue—what if a subscriber of one CDN wants to access content in a different CDN? To solve this problem, the Content Bridge is a vendor consortium of CDNs and CDPs whose aim is to move toward developing new protocols to enable interoperability between different CDNs so that a subscriber of one CDN can access content from the network of a different CDN. The Internet Engineering Task Force (IETF) is also working on a number of draft protocols to support interoperability between different CDNs.

Content delivery network (CDN). A simple example of how a CDN works.

Marketplace

Since Akamai blazed the path, a plethora of new CDNs have arisen and are vying for market dominance. These include

- CDNs built by private companies such as Yahoo! that have put together their own custom CDNs using technologies from vendors such as Cisco Systems.
- Companies such as Inktomi Corporation, Cache-Flow, and Network Appliance that create hardware and software tools that can be used to build custom CDNs.
- Pure-play CDPs who build virtual CDNs by leasing bandwidth needed to push out their content to cache servers from bandwidth providers (BPs) such as Exodus Communications and Globix Corporation.

Despite the proliferation of CDN vendors and solution providers, Akamai and Inktomi, two early comers to the market, have established their platforms as cornerstone solutions for many large ISPs and enterprise customers.

Akamai has more than 4000 caching servers distributed at POPs in over 50 countries. Other prominent players include new companies such as Digital Island. Existing networking companies are also releasing CDN solutions to the marketplace, though, including Cisco and Lucent Technologies.

A number of vendors are offering turnkey CDN solutions that can be easily implemented to improve content hosting performance for corporate intranets, ISPs, carriers, and others who need it. A leading vendor of CDN-in-a-box solutions is EdgeStream.

C

content filter

A component of Microsoft Indexing service that can read a specific document format and turn it into a stream of text characters.

Overview

Content filters are an essential part of the indexing process on Indexing service because they determine which types of documents can be read and indexed. Indexing service includes content filters for popular file formats such as

- ASCII text
- Hypertext Markup Language (HTML) pages
- Microsoft Word documents
- Microsoft Excel spreadsheets

In addition, many third-party companies have produced content filters for their own document formats, allowing these documents to be indexed by Indexing service when their content filters have been installed. Content filters also handle the presence of embedded objects in documents and recognize when a language shift occurs in a multilingual document.

contention

A condition that occurs when two or more stations on a network try to access the network medium simultaneously. In other words, the stations are contending for control of the medium.

Overview

There are different ways of resolving contention issues on a network. One way is to use a single station as the master or primary station that controls all communication on the network. Other devices on the network function as slave, or secondary, stations. The entire system is known as a master-slave system. The master station normally functions in transmit mode, while the slave stations operate in receive mode. The master station tells individual slave stations when they should switch to transmit mode in order to transmit information over the network. This kind of scenario is used in networks based on IBM's Systems Network Architecture (SNA).

In Ethernet networks, the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) method is used to resolve contention on the network by allowing collisions to occur, and then resolving them successfully.

See Also: *Carrier Sense Multiple Access with Collision Detection (CSMA/CD)*

content rating

A mechanism for preventing users of Microsoft Internet Explorer from viewing Web sites that contain objectionable language, violence, nudity, or sexually explicit content.

Overview

These ratings are configured on the Web server on a site-by-site basis. Ratings for each category have been established at four levels of acceptable use. The Webmaster who creates the site can then include information about the levels of objectionable language, violence, nudity, or sexually explicit content present on their site. Content ratings are defined by the Recreational Software Advisory Council (RSAC). The user can configure her browser to a specified accessibility level for each type of content by using the Content Advisor feature of Internet Explorer.

For More Information

RSAC can be found at www.rsac.org.

control message

A command sent from one Usenet host to another.

Overview

Control messages are defined in the Network News Transfer Protocol (NNTP) specifications. Control messages can be issued by Usenet hosts to perform actions such as

- Creating a new newsgroup on the host
- Deleting a newsgroup
- Canceling messages that have already been posted

Control messages are simple text commands. You can troubleshoot a Usenet host by using telnet to connect to

port 119 and manually typing various control messages and examining their results.

Control Panel

A Microsoft Windows feature consisting of a number of utilities for configuring hardware devices and operating system services.

Overview

The following table shows some of the more common Control Panel utilities in Windows 95, Windows 98, Windows NT, Windows 2000, Windows XP, and Windows .NET Server and briefly describes their function. Note that some utilities are named differently in the various Windows versions, such as 32-bit ODBC for Windows NT and ODBC (32 bit) for Windows 95 or 98; these utilities are listed separately here. Note also that some Control Panel utilities are present only when additional Windows components have been installed. For example, the GSNW utility is present only when Gateway Services for NetWare has been installed. Finally, installing additional third-party software can add new utilities to Control Panel associated with that software.

control set

Refers to a set of registry keys in Microsoft Windows 2000, Windows XP, and Windows .NET Server that contain configuration information used for system startup.

Overview

Control sets define certain aspects of the Windows 2000, Windows XP, and Windows .NET Server boot process to allow Windows 2000, Windows XP, and Windows .NET Server to boot up successfully. Up to four control set subkeys are located under the HKEY_LOCAL_MACHINE\SYSTEM registry key, including the following:

- ControlSet001, ControlSet002, and so on, which represent backup copies of control sets that successfully started the system.
- CurrentControlSet, which refers to the control set that was used to successfully boot the system under its current configuration. The key here is a pointer to one of the ControlSet00x registry keys.

The Select registry key found under HKEY_LOCAL_MACHINE\SYSTEM identifies which of the control set keys corresponds to the current, default, failed, and Last Known Good configurations. If the current control set cannot start the system, you can press the Spacebar when indicated during the boot process to select the last known good configuration, which is the last control set that worked for sure.

convergence

The process of updating routing tables after a change in the routing topology of an internetwork.

Overview

When a change occurs in the routing infrastructure of an internetwork, information concerning the change needs to be replicated to all routers that need to know about it. The process by which all routers gradually become aware of the change that occurred is called convergence.

Examples of occurrences that affect the routing infrastructure of an internetwork include adding a new

router to the network, having an existing router fail on the network, and adding a new route to the routing table of a router on the network. When any of these situations arise, the routing protocol used to provide communications between the routers on your network is used to communicate these changes to all the routers that need to be aware of them. It typically takes time (from minutes to hours) for such changes to propagate completely through the internetwork's routing infrastructure, and as routers become updated with the new routing information, the network is said to "converge" toward its final state.

Convergence is important—if it does not occur fully, some routes may be unavailable on the network, making some parts of the network inaccessible. Furthermore, some packets may end up disappearing into "black holes" instead of arriving at their destination.

Notes

A more popular usage of the term *convergence* is to describe the merging of voice, data, and video services for transmission over a single network.

cookie

A small text file that the Web server saves the Web browser during a Hypertext Transfer Protocol (HTTP) session.

Overview

Cookies were originally intended to enable session state information to be maintained for Web applications across multiple HTTP requests. However, most commercial Web sites also use cookies to record information about the client's usage patterns, including the date and time the client visited the site, which pages were accessed, and Web browser preferences. Other uses for cookies include providing custom or personalized pages for users visiting Web sites, targeting advertising to users according to the pattern of their previous visits to a site, and enabling online shopping carts to function.

Cookies use the storage system of the client for saving this information instead of storing it on the server. Because the vast number of clients might visit the site

C

only once, it would be inefficient to dedicate a large portion of server storage to tracking anonymous clients who might never return. Furthermore, client preferences (such as IP address) might change between sessions, especially for dial-up clients, so servers would have no way of recognizing clients if cookie information were saved on the server. Cookies therefore provide a way for the server to recognize that the client previously visited the site and record what the client did during previous visits, allowing the server to customize the HTTP session to meet the needs of the client (or the needs of the site's advertisers!).

Cookies are harmless text files and cannot be used to transmit a virus to the client. Cookies are simply passive holders of information; they cannot be used by hackers and other unauthorized users to "get" information off your computer such as your e-mail address. Nevertheless, most Web browsers, such as Microsoft Internet Explorer, have an optional setting that allows users to reject cookies. However, rejecting cookies can result in poorer browsing experiences on sites that are cookie-dependent. You can also delete any cookies on a computer running Microsoft Windows by deleting the contents of the Cookies subdirectory within the user profile directory on your hard drive (do not delete the directory itself, however!).

Notes

Web applications written using Microsoft Active Server Pages (ASP) technology can use cookies for maintaining session state information.

Shareware sites offer a variety of third-party browser plug-ins for managing or disabling cookies.

copper cabling

One of the two basic types of physical cabling media (the other being glass, or fiber-optic, cabling).

Overview

Copper cabling is cheap and flexible, but it is susceptible to electromagnetic interference (EMI), has limited range because of attenuation, and generates electromagnetic radiation that can be intercepted by nearby equipment.

The types of copper cabling commonly used in networking include

- Twisted-pair cabling, such as unshielded twisted-pair (UTP) cabling and shielded twisted-pair (STP) cabling
- Coaxial cabling, such as thinnet and thicknet

For more information on these types of copper cabling, refer to their individual entries in this book.

Implementation

UTP cabling of Category 5 (Cat5) grade is the most commonly used copper cabling in networking environments today. Cat5 cabling comes in either solid core or stranded cabling. Solid core cabling is stiffer, but it has better conductivity and less attenuation, and it is simpler to terminate than stranded cabling. Stranded cabling is more flexible and easier to work with than solid cabling, and it is more resistant to breaking or fracturing. Use solid core UTP cabling for fixed horizontal cable runs, cross-connections, and backbone cabling; use stranded UTP cabling for locations where equipment is frequently moved, for short cable runs between computers and wall plates, or as patch cables in the wiring closet.

Copper Distributed Data Interface (CDDI)

A form of Fiber Distributed Data Interface (FDDI) deployed over copper cabling instead of fiber.

Overview

Copper Distributed Data Interface (CDDI) can send data over unshielded twisted-pair (UTP) cabling at 100 megabits per second (Mbps), but cable lengths are limited to about 330 feet (100 meters). The architecture and operation are similar to FDDI, but CDDI is not as commonly implemented as FDDI (and because FDDI is usually considered a legacy networking architecture now, CDDI is also likely to fade away quickly).

If cost is an issue, CDDI offers an alternative to FDDI. CDDI still provides a 100-Mbps network with redundancy, but at reduced cost because copper cabling is

cheaper than fiber-optic cabling. Note that CDDI does not provide the security that FDDI does: copper cabling can be tapped, but fiber-optic cabling cannot.

copy backup

A backup type in which all the selected files and folders are backed up, but the archive attribute is not marked for each file and folder.

Overview

Copy backups (or simply copies) do not interrupt the normal backup schedule because they do not change the state of the archive bit on files being backed up. Copy backups are typically used to produce additional copies of backup tapes. Copy backups might be used for

- Archiving information in a different location
- Generating tapes of month-end financials, which can then be given to the accounting department
- Providing branch offices with copies of information on file servers

See Also: *backup, backup type*

copying files

Making a replica of files.

Overview

On Microsoft Windows platforms, files can be copied using a graphical user interface (GUI) tool such as Windows Explorer or from the command prompt using the copy command. Some inheritance issues are associated with copying files on Windows NT, Windows 2000, Windows XP, and Windows .NET Server platforms that use the NTFS file system (NTFS). Specifically, copying a file within or between different NTFS volumes causes the file to inherit the permissions of the folder into which it is copied. For example, if a file on the NTFS drive C has read permission for everyone and it is copied to a directory on the NTFS drive D, which has change permission for everyone, the copy of the file inherits the change permission from the directory it is moved to.

CORBA

Stands for Common Object Request Broker Architecture, a component architecture that specifies technologies for creating, distributing, and managing component programming objects over a network.

See: *Common Object Request Broker Architecture (CORBA)*

Core-Based Trees (CBT)

A multicast routing protocol.

Overview

Internet Protocol (IP) multicasting relies on the spanning tree algorithm to ensure delivery of information to intended recipients. Spanning-tree technologies can be implemented in two basic ways:

- **Dense mode:** Used for Webcasting and other large-scale multicast events.
- **Sparse mode:** Used for delivering multicast information to specific, small pockets of users on a large internetwork.

Core-Based Trees (CBT) is one of two sparse-mode protocols commonly used, the other being Protocol Independent Multicast Sparse Mode (PIM-SM).

Architecture

CBT works by having a single core router create a single multicast routing tree, regardless of the multicast transmission's source. Then, when a multicast client wants to register to receive a multicast transmission, the client contacts the nearest upstream multicast router by sending an Internet Group Membership Protocol (IGMP) packet to the router. If the member router is already receiving the multicast transmission, it registers the client and forwards the transmission to the client. If the router is not receiving the transmission, it contacts the next router upstream, and this continues until, if necessary, the core router is reached. The core router then adds the member routers to the multicast group and forwards the transmission to the member router, which then passes it to the client.

C

counter

An aspect of an object in Performance for which usage statistics can be collected.

Overview

Performance is a Microsoft Windows 2000, Windows XP, and Windows .NET Server administrative console for monitoring system resources. It can be used to collect status information about various objects. For example, if the object Processor is being studied, the Performance Monitor collects information on all counters that belong to this object. This includes counters such as

- **% User Time:** The percentage of the time the processor is in user mode executing a nonidle thread
- **% Privileged Time:** The percentage of the time the processor is in kernel mode executing a nonidle thread
- **Interrupts/sec:** The number of device interrupts a processor receives per second

If the machine is a multiprocessor system, each instance of each counter can be monitored. Performance Monitor counters are usually one of two types:

- Instantaneous counters, which display the most recent value of a measurement— for example, Processor: % Processor Time
- Average counters, which display the average of the last two measured values— for example, LogicalDisk: Avg. Disk Bytes/Read

country code

A two-letter code identifying top-level domains for countries and regions in the Domain Name System (DNS).

Overview

Country codes are a way of geographically identifying a domain name as belonging to a particular country or region. They are an alternative to the more commonly used organizational codes such as .com, .org, and .net. This table lists the various country codes in the DNS system.

coupler

A small device for connecting two cables to make a longer cable, sometimes called an inline coupler.

Overview

Inline couplers do not provide any amplification or signal boost, and can cause attenuation and signal degradation unless they are of high quality. One example would be a small box that accepts two Category 5 (Cat5) cables with RJ-45 connectors and links them to form a longer cable. Another example would be the BNC barrel connector for joining two lengths of thinnet cabling. A third example would be a coupler with two RJ-11 connectors for joining two phone lines.

Coupler. A Category 5 UTP (unshielded twisted-pair) coupler.

The term *coupler* is also used to refer to modular connectors that can snap into customizable patch panels to allow different kinds of cabling to be mixed in one patch panel.

CPE

Stands for customer premises equipment (CPE), telecommunications equipment that is installed at the customer's location.

See: customer premises equipment (CPE)

CRC

Stands for cyclical redundancy check, an error-checking technique for ensuring packets are successfully delivered over a network

See: cyclical redundancy check (CRC)

Creator Owner

A Microsoft Windows 2000, Windows XP, or Windows .NET Server built-in identity that is used as a security context for running services and operating system functions.

Overview

The membership of the Creator Owner system group cannot be modified directly. The Creator Owner system group includes only the user who created or took ownership of a network resource and is functionally equivalent to that user's primary group. The Creator Owner system group has full permissions on the resource, but the rights of the Creator Owner system group cannot be modified. Whoever creates a file system object or print job becomes the Creator Owner of that object or job.

See Also: built-in identities

credentials

Information required from users who want to log on to a network and access its resources.

Overview

Credentials, which are formed by combining a user's username and password, identify users so that they can

be authenticated by the network security provider. Credentials for access to one network do not guarantee access to another network.

In networks that are based on Microsoft Windows NT, Windows 2000, and Windows .NET Server, computers called domain controllers are responsible for authentication of user's credentials. In addition, trust relationships can be established between Windows NT domains to allow user's credentials to be authenticated from anywhere in the enterprise. Windows NT, Windows 2000, Windows XP, and Windows .NET Server support single-user logon, which allows a user to use a single set of credentials for accessing resources anywhere on a network.

See Also: authentication protocol, password, username

crimper

A cabling installation tool used for attaching connectors to cabling.

Overview

Crimpers are used to terminate cables by applying appropriate pressure to contacts within a connector so that it remains physically attached to the cable without soldering. A crimper is an essential component of a network administrator's toolkit. Crimpers can include built-in strippers for removing the outer insulation from a cable. They can include a set of dies for crimping different kinds of connectors, or they can be specialized for a single type of termination. Crimpers are most often used for terminating Category 5 (Cat5) unshielded twisted-pair (UTP) cabling with RJ-45 connectors. A good crimper should be made of heavy-duty metal and be able to cut, strip, and terminate a cable easily.

Crimper. A crimper with connector set.

CRL

Stands for certificate revocation list, a list, maintained by a certificate authority (CA), of digital certificates that have been issued and then later revoked.

See: certificate revocation list (CRL)

CRM

Stands for Customer Relations Management, a type of business application used to manage business-to-consumer (B2C) connections

See: Customer Relationship Management (CRM)

crossover cable

Twisted-pair cabling with the send and receive pairs of wires crossed.

Overview

Crossover cables are primarily used for connecting hubs to each other. In addition, a small, two-station local area

C

network (LAN) can be established by connecting two computers together with 10BaseT network interface cards (NICs) and a crossover cable. This configuration is often utilized when one computer is used to test the networking functions of another because it allows the computer being tested to be isolated from the network. The illustration shows the pinning configuration of a crossover cable.

Crossover cable. Pinning for a crossover cable.

See Also: cabling, twisted-pair cabling

crosstalk

A form of interference in which signals in one cable induce electromagnetic interference (EMI) in an adjacent cable.

Overview

The ability of a cable to reject crosstalk in Ethernet networks is usually measured using a scale called near-end crosstalk (NEXT). NEXT is expressed in decibels (dB), and the higher the NEXT rating of a cable, the greater its ability to reject crosstalk. A more complex scale called Power Sum NEXT (PS NEXT) is used to quantify crosstalk in high-speed Asynchronous Transfer Mode (ATM) and Gigabit Ethernet (GbE) networks.

The twisting in twisted-pair cabling reduces the amount of crosstalk that occurs, and crosstalk can be further reduced by shielding cables or physically separating them. Crosstalk is a feature of copper cables only—fiber-optic cables do not experience crosstalk. Crosstalk can be a problem for unshielded twisted-pair (UTP) cabling. To minimize crosstalk, make sure that

- You do not untwist or sharply bend the UTP cabling

- The cable ends connected to a patch panel or wall plate are untwisted no more than 0.5 inch (1.3 centimeters)

See Also: cabling, near-end crosstalk (NEXT)

CryptoAPI

A core component of the latest versions of Microsoft Windows that provides application programming interfaces (APIs) for cryptographic security services that provide secure channels and code signing for communication between applications.

Overview

CryptoAPI provides a set of standard Win32 libraries for managing cryptographic functions using a single consistent interface independent of the underlying cryptographic algorithms and ciphers. CryptoAPI interfaces with modules called cryptographic service providers (CSPs), such as the Microsoft RSA Base Cryptographic Provider, to provide cryptography functions such as hashing, data encryption and decryption, key generation and exchange, digital signature issuance and verification, and so forth.

CryptoAPI is natively supported by the latest versions of Windows NT, Windows 98, Windows 2000, Windows XP, and Windows .NET Server. Microsoft Internet Explorer version 4 provides CryptoAPI support for Windows 95. The current version of CryptoAPI is version 2.

Cryptographic Message Syntax Standard

A standard that defines the general syntax for data that includes cryptographic features such as digital signatures, encryption, and certificate chains.

Overview

Cryptographic Message Syntax Standard, also known as PKCS #7, specifies the format in which the data is signed and encrypted, and the types of encryption algorithms used.

Data encrypted according to the PKCS #7 standard can have multiple digital certificates attached, including certificate revocation lists (CRLs). Certificates include

information concerning the issuer and serial number of the public key of the signer so that the recipient can decrypt the message.

See Also: *cryptography, digital certificate, encryption*

cryptography

In networking and telecommunications, the process of securely transmitting data over a network in such a way that if the data is intercepted, it cannot be read by unauthorized users.

Overview

Cryptography involves two complementary processes:

- **Encryption:** The process of taking data and modifying it so that it cannot be read by distrusted users.
- **Decryption:** The process of taking encrypted data and rendering it readable for trusted users.

Encryption and decryption are performed using algorithms and keys. An algorithm, a series of mathematical steps that scrambles data, is the underlying mathematical process behind encryption. There are a variety of cryptographic algorithms that have been developed based on different mathematical processes.

Some algorithms result in stronger encryption than others—the stronger the algorithm, the more difficult the encrypted data is to crack. For example, Network and Dial-up Connections in Microsoft Windows 2000 supports standard 40-bit RAS RC4 encryption, but if you are located in the United States or Canada, you can get a stronger 128-bit version. Similar versions are offered for Windows NT.

Encryption algorithms involve mathematical values called keys. Earlier cryptography systems were secret key encryption systems in which only the hosts involved in transmitting and receiving the encrypted transmission knew the key. This key had to somehow be transported securely to anyone needing to decrypt a message. This was the main disadvantage with secret key cryptosystems.

Most cryptography today involves a process called public key encryption, which uses two different keys:

- A public key that is distributed to any user (or to any client program) requesting it
- A private key that is known only to the owner (or the owner's client program)

To send an encrypted message, the sender uses his or her private key to encrypt the data, and the recipient uses the sender's public key to decrypt it. Similarly, the recipient can return a response to the original sender by using the sender's public key to encrypt the response, and the original sender uses his or her private key to decrypt it.

CSMA/CA

Stands for Carrier Sense Multiple Access with Collision Avoidance, the media access control method used by AppleTalk.

See: *Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA)*

CSMA/CD

Stands for Carrier Sense Multiple Access with Collision Detection, the media access control method used by half-duplex Ethernet networks.

See: *Carrier Sense Multiple Access with Collision Detection (CSMA/CD)*

CSNW

Stands for Client Services for NetWare, a Windows 2000, Windows XP, and Windows .NET Server service that provides Microsoft Windows clients with access to Novell NetWare file, print, and directory services.

See: *Client Services for NetWare (CSNW)*

CSP (caching service provider)

Stands for caching service provider, a company that maintains caching servers that speed the transfer of information across the Internet's infrastructure and offers managed access to these servers for a fee.

See: *caching service provider (CSP)*

CSP (commercial service provider)

Stands for commercial service provider, typically Internet service providers (ISPs), online service providers, telephone and cable network operators, and other companies.

See: commercial service provider (CSP)

CSS

Stands for cascading style sheets, a method for giving Web developers more control over how the pages of a Web site will look when displayed on a Web browser.

See: cascading style sheets (CSS)

CSU

Stands for Channel Service Unit, a device that is used to connect a synchronous digital telecommunications line to a computer network.

See: Channel Service Unit (CSU)

CSU/DSU

Stands for Channel Service Unit/Data Service Unit, a device that combines the functions of both a Channel Service Unit (CSU) and a Data Service Unit (DSU).

See: Channel Service Unit/Data Service Unit (CSU/DSU)

.csv file

A text file having the extension .csv, which contains fields of data separated by commas and a carriage return/linefeed at the end of each record. The extension .csv stands for comma-separated values.

Overview

These files are often used as a standard format for importing and exporting information between applications. For example, in Microsoft Exchange Server you can modify the properties of a group of mailboxes by exporting the properties of the mailboxes to a .csv file, opening this file as a spreadsheet in Microsoft Excel, modifying the properties using string functions and search/replace, exporting the information back into another .csv file, and then importing the modified file

back into Exchange. Many applications can export log files or other information as .csv files. These files can then be imported into a spreadsheet or database program where they can be subjected to further inspection and analysis. Graphics and charts can also be generated from the imported information.

CTEC

Stands for Certified Technical Education Center, an education-delivery company such as a school or training center that is been qualified by Microsoft Corporation for the delivery of Microsoft Official Curriculum (MOC) courseware.

See: Certified Technical Education Center (CTEC)

CTI

Stands for computer-telephony integration, a general term describing the integration of computer and telephone technologies.

See: computer-telephony integration (CTI)

Ctrl+Alt+Delete

A control sequence that has different effects depending upon the operating system involved.

Overview

Holding down the Control, Alt, and Delete keys simultaneously produces the following results (depending upon the operating system being used):

- **MS-DOS:** Restarts the computer.
- **16-bit Microsoft Windows, Windows 95, and Windows 98:** Shows running tasks and allows you to terminate a task. A second Ctrl+Alt+Delete will restart the computer.
- **Windows NT:** Brings up the Windows NT Security dialog box.
- **Windows 2000:** Brings up the Windows Security dialog box.
- **Windows XP and Windows .NET Server:** Brings up the Windows Security dialog box.

custom authentication

Any user-created method for authentication of clients on a network.

Overview

Microsoft Internet Information Services (IIS) lets you create custom authentication schemes to control access to Web content. These can be implemented using several different technologies, including Active Server Pages (ASP), Internet Server API (ISAPI) authentication filters, or Common Gateway Interface (CGI) applications. For example, using any of these technologies, you can create an authentication scheme to

- Perform a search of a client's credentials in a custom user database
- Examine a client's digital certificate to determine whether to allow access
- Use cookies or some other mechanism to establish whether the client should be authenticated

Customer Information Control System (CICS)

Customer Information Control System (CICS) enables transaction-based applications to operate on IBM mainframe systems. More than half of all mainframes running today still use some CICS applications. Traditionally CICS-based applications are accessed using legacy IBM 3270 text-based terminals, but newer products allow CICS transactions to be wrapped in Hypertext Markup Language (HTML) for access by Web browsers. One such product is Shadow AutoHTML for CICS/TS from Neon Systems, which also supports Open Database Connectivity (ODBC) interfaces for CICS applications.

customer premises

A general term referring to your local company's networking environment.

Overview

The term *customer premises* is typically used by service providers who provide leased or contractual services to help you implement and support your network. For example, a cabling company would install cabling at your customer premises and call this installation "premise wiring." A telecommunications company might send a representative to a customer premises in order to install a Channel Service Unit/Data Service Unit (CSU/DSU) or other device in the wiring closet to enable wide area network (WAN) communication. Typically, your company is responsible for the physical security of such installed equipment, but the actual configuration and monitoring of the equipment often takes place at the telco's central office (CO).

See Also: *customer premises equipment (CPE)*, *enterprise resource planning (ERP)*

customer premises equipment (CPE)

Telecommunications equipment that is installed at the customer's location.

Overview

Customer premises equipment (CPE) is installed to terminate wide area network (WAN) links and local loop connections between the customer and the carrier's central office (CO) and to route traffic between the customer premises and the carrier from which telecommunications services are leased. Common examples of customer premises equipment include telephones, modems, Channel Service Unit/Data Service Units (CSU/DSUs), Private Branch Exchanges (PBXs), and Integrated Access Devices (IADs) routers.

Generally, the telecommunications service provider is responsible for configuring and monitoring the equipment, which is purchased or leased by the customer from the carrier. For example, when installing a CSU/DSU as a termination for a T1 line, the configuration of the CSU/DSU is likely to have been done previously by the service provider. The carrier then uses Simple Network Management Protocol (SNMP) and loopback monitoring to determine, from its central office, whether the remotely installed equipment is functioning correctly.

C

Alternatively, customers may purchase or lease their own CPE from third-party vendors. In this case the customer is usually responsible for configuring and monitoring the equipment. In general, cost/benefit is usually on the side of leasing CPE from the provisioning carrier because the cost of replacing defective or failed equipment or upgrading equipment to support enhanced services is the burden of the carrier.

Customer Relationship Management (CRM)

A type of business application used to manage business-to-consumer (B2C) connections.

Overview

Customer Relationship Management (CRM) software is used to manage mission-critical business information concerning the direct relationship between a business and its clients. CRM enables business users to quickly and easily access up-to-date information concerning client accounts, and it provides the tools for managing and growing a company's relationship with its customers. CRM software enables a business to manage leads, distribute timely information to customers, and coordinate a multitude of other customer-centric activities.

Marketplace

Some of the bigger players among CRM vendors include Onyx Technology, Pivotal Software, and Siebel Systems. CRM software takes a variety of forms depending on whether it is being implemented in small, mid-sized, or enterprise-level businesses. Some CRM vendors build their products around customer databases, while newer players and CRM startups often use the application service provider (ASP) model for outsourcing CRM needs.

The worldwide market revenue for all forms of CRM software and services was estimated at over \$10 billion in 2000 and may reach \$25 billion by 2003, according to some analysts.

Notes

A recent offshoot of CRM is partner relationship management (PRM), which helps companies to manage the more indirect relationship they have with business channels and supply chain partners, among others.

Besides the big CRM players, a number of emerging pure-play PRM vendors are attracting market share. These include Allegis, ChannelWave, and many others.

custom recipient

A recipient in Microsoft Exchange Server that does not reside in the Exchange organization.

Overview

When creating a custom recipient, you specify the e-mail address of the remote user first, and then configure the properties of the recipient. An example of a custom recipient is the Simple Mail Transfer Protocol (SMTP) address of a user on the Internet.

Custom recipients are often created on Exchange servers to place frequently used foreign addresses in the global address book so that users do not have to specify the recipient's e-mail address manually or maintain their own personal address books. Custom recipients can be used for various other purposes in Exchange, such as to enable a user's Internet mail to be forwarded to his or her Exchange mailbox.

cyclical redundancy check (CRC)

An error-checking technique for ensuring that packets are successfully delivered over a network.

Overview

A cyclical redundancy check (CRC) is a number that is mathematically calculated for a packet by its source computer and then recalculated by the destination computer. If the original and recalculated versions at the destination computer differ, the packet is corrupt and needs to be resent or ignored.

The mathematical procedure for performing a CRC is specified by the International Telecommunication Union (ITU) and involves applying a 16-bit polynomial to the data being transmitted by the packet for packets of 4 KB of data or less, or a 32-bit polynomial for packets larger than 4 KB. The results of this calculation are appended to the packet as a trailer. The receiving station applies the same polynomial to the data and compares the results to the trailer appended to the packet. Implementations of Ethernet use 32-bit polynomials to calculate their CRC.

DAB

Stands for Digital Audio Broadcasting, a specification for broadband digital radio.

See: Digital Audio Broadcasting (DAB)

DACL

Stands for discretionary access control list, an access control list (ACL) that can be configured by administrators.

See: discretionary access control list (DACL)

daemon

The UNIX equivalent of a Microsoft Windows 2000, Windows XP, or Windows .NET Server service.

Overview

A daemon is a program associated with the UNIX operating system that runs in the background and performs some task without instigation from the user. An example of a daemon is the telnet daemon, which runs continuously in the background, waiting for a connection request from a telnet client. The telnet daemon facilitates the remote connection and makes it possible for the user to control the machine.

Daemon. How the nfsd daemon works.

Another example is the HTTPd daemon for the Apache Web server, which waits for Hypertext Transfer Protocol (HTTP) requests from Web browser clients and fulfills them.

A third example of a daemon is the nfsd daemon, which supports the remote file access aspect of the Network File System (NFS) in a UNIX environment. The nfsd daemon runs in the background on UNIX servers, waiting for remote procedure calls (RPCs) from NFS clients.

Daemons typically use RPCs for communication with clients. Because NFS is implemented as daemon processes at the user level instead of at the kernel level, NFS is thread-safe for execution, allowing multiple NFS processes to run as independent threads of execution.

Notes

The Microsoft equivalent of daemon is service. For example, the Workstation service of Windows 2000 would be known in UNIX as a daemon instead of a service.

daily copy

A type of tape backup in which only files and folders that have changed on that day are backed up.

Overview

When a daily copy is performed during a backup, files and folders modified on that day are backed up but their archive attribute is not marked.

Daily copies are not a common type of backup operation. They are typically used only if a user wants to take home copies of the files she has been working on during the day. Few administrators would be willing to schedule and run the system backup software just to make copies of these files, so users taking advantage of this backup type usually have a locally attached backup

device along with a similar device attached to their systems at home.

Daily copy backups are likely to be performed on media such as Iomega Zip or Jaz disks rather than on tape.

Notes

Daily copy backups are supported by the Microsoft Windows 2000 Backup utility.

dark fiber

Any fiber-optic cabling or fiber device such as a repeater that is installed but not currently in use.

Overview

When no light is being transmitted through fiber-optic cabling, it is called dark fiber since it is, in effect, dark. When a carrier or cabling company first provisions fiber, it is called dark fiber. Then once all the components of the system are installed, including connectors,

amplifiers, repeaters, switches, routers, and such, the light can be turned on and the fiber is no longer dark. Dark fiber is thus simply unused fiber or fiber that is not yet ready to be used.

Before dark fiber is activated, the system is usually tested using an optical time domain reflectometer (which measures and analyzes a fiber link) and other measuring devices to determine whether the system has integrity, and to measure its bandwidth and attenuation parameters.

Implementation

When an enterprise needs a fiber connection for wide area usage, it can take three possible approaches:

- **Lay their own fiber:** This is an expensive solution, not only because large amounts of fiber may be required, but also because expertise in fiber-optic cabling technologies is needed and is often in short supply. Right of way must also often be purchased in order to lay the fiber, and this is often difficult or downright impossible. Only the largest enterprises can afford this approach, and it is rarely implemented beyond campus networks.
- **Lease dark fiber:** This involves paying a telecommunications carrier for one or more strands of fiber-optic cabling from the carrier's own system. Companies that want to maintain total control of their wide area network (WAN) links can choose this route. They first lease dark fiber from a carrier, and then install switches and repeaters to build their own long-haul fiber-optic network. Leasing dark fiber was a popular solution for many enterprises in the 1990s, especially for financial institutions that required the highest level of privacy and security for their WANs. Also, in the 1990s carrier networks were almost exclusively Asynchronous Transfer Mode/Synchronous Optical Network (ATM/SONET)-based, and the WAN services they offered were expensive; enterprises saw leasing dark fiber as a way of controlling costs and simplifying their WANs.
- **Leasing managed wavelength services:** With the advent of dense wavelength division multiplexing

(DWDM) on carrier networks at the end of the 1990s, the carrying capacity of carrier networks increased dramatically. This, and the emergence of new carriers such as Metropolitan Gigabit Ethernet providers, drove down the cost of carrier WAN services, making leasing WAN services more cost attractive to some enterprises than leasing their own dark fiber. New providers called managed wavelength services providers quickly arose as resellers of fiber capacity from traditional carriers. Some of these managed wavelength services providers include 360networks, Global Crossing, Level 3, Metromedia, XO Communications, and others. AT&T also directly leases managed wavelength services up to 2.4 gigabits per second (Gbps) to large companies.

Notes

Although the term *dark fiber* at first sounds like there is a problem in the fiber-optic cabling system, this is not the case. However, various problems can occur in a fiber-optic cabling system that can cause it to remain dark once the system is turned on. These can include the following:

- Microfractures in the glass core or cladding caused by improper installation techniques, such as excessive bending or stretching of a segment of cable
- Improper terminations for the fiber or loose connectors
- Malfunctioning repeaters

Data Access Objects (DAO)

A Microsoft technology that enables you to use a programming language to access and manipulate data stored in both local and remote databases.

Overview

Data Access Objects (DAO) lets you access and manage databases, along with their structure and objects, by providing a framework called an object model that

uses code to create and manipulate different kinds of databases.

DAO supports two different interfaces, which are known as workspaces:

- **ODBCDirect workspace:** This lets you can access database servers such as Microsoft SQL Server through open database connectivity (ODBC). This workspace lets you execute queries or stored procedures against a database server, perform batch updates, and execute asynchronous queries. ODBCDirect makes it possible for you to take advantage of Remote Data Objects (RDO) technology in your DAO code.
- **Microsoft Jet workspace:** This lets you access databases based on Jet technology or on installable indexed sequential access method (ISAM) data sources in other formats such as Paradox, dBase, and Btrieve. You use this workspace to access a single database, such as a .mdb database from Microsoft Access, or to join together data originating from several different database formats.

Prospects

DAO and RDO are both available now, but these technologies are being superseded by Microsoft ActiveX Data Objects (ADO) and Remote Data Service (RDS). All these components can be found in the Microsoft Data Access Software Development Kit.

data alarm

A device for alerting network administrators to network problems relating to serial transmission.

Overview

Data alarms typically monitor serial lines such as RS-232 connections for the presence or absence of certain signals. For example, you can monitor the connection between a print server and its attached printer or between an access server and a modem or a Channel Service Unit/Data Service Unit (CSU/DSU).

D

Data alarm. Implementing a data alarm for alerting administrators to problems with serial links.

A data alarm can be a simple device that monitors one serial line for the presence or absence of data. If the data flow stops, a flashing LED or audible alarm signals the problem to the administrator. More complex data alarms can support multiple serial lines or other serial interfaces such as RS-449 and V.35, can have programmable functions and menu-driven commands, and can monitor other devices, such as Time to Live (TTL) devices. These more complex devices can be configured to dial a remote station when a problem arises and to generate a report of the condition or even activate an alphanumeric pager.

Notes

Some vendors use the term *data alarm* to describe a device that senses network problems associated with the flow of data in other networks such as Ethernet.

database

In its simplest form, a file used to store records of information, with each record containing multiple data fields. More generally, any application used to manage structured information.

Overview

Databases are an essential component of every business, representing the back-end of a company's information structure. Databases are used to store a broad range of information including inventory, customer contacts, sales records and invoices, catalogs, and so on. Without databases, modern businesses could not operate with the scope and range that they have, as they would be overwhelmed with information they could not manage.

Databases allow information to be stored, updated, manipulated, and queried. Sales figures for a given month can be extracted from a database using a standard programming language for building queries called Structured Query Language (SQL), versions of which are built into products from every database vendor.

Implementation

The most popular type of database is the relational database, in which the records are stored in tables that are related to each other using primary and foreign keys. A primary key is the field in each record that uniquely defines the record. (For example, a part number might be used as the primary key in a table that holds the price of each item a company sells.) A foreign key is a field in another table that matches the first table's primary key, creating a relationship between the two. An application for creating and managing relational databases is called a relational database management system (RDBMS).

Records are like the rows of a table. Each record is a collection of information about some physical system or logical object. Field names are like the column names of a table. Each field name represents a property or attribute of the system or object. Databases are widely used by businesses for storing information about inventory, orders, shipping, accounting, and so forth.

Microsoft SQL Server is Microsoft Corporation's enterprise-level RDBMS. SQL Server databases are stored on devices. Each computer running SQL Server has

four system databases plus one or more user databases installed on it. The system databases are as follows:

- The master database, which is used for tracking system-wide information.
- The tempdb database, which is used for temporary working storage and sort operations.
- The model database, which is a template for creating new databases.
- The msdb database, which is used to store system data and transaction logs and to support the SQL Server Agent service and its scheduling information. The msdb database is stored on two devices, the Msdbdata system device and the Msdblog system device.

Marketplace

Major players in the enterprise database market include Microsoft Corporation with its SQL Server, Oracle Corporation with its Oracle 9i, IBM with its DB2, and others. These database products frequently compete for mindshare in the enterprise arena by surpassing each other in TCP-C benchmark figures.

Competing with these major players are open-source databases such as MySQL from NuSphere Corporation and PostgreSQL from Great Bridge, which run on the Linux and Berkeley Software Distribution (BSD) platforms and build upon the stability of those platforms.

Given the ubiquity and importance of databases to business, a wide spectrum of tools is available for planning, implementing, managing, tuning, monitoring, and troubleshooting database platforms. For example, pocketDBA has a module for the wireless Palm OS handheld device which allows an administrator to remotely monitor and manage Oracle databases using a Palm. Similar applications will soon be available for the PocketPC platform as well.

Notes

The term *database* can have different meanings for different vendors. In Oracle products, for example, *database* refers to the entire Oracle DBMS environment. In SQL Server, databases provide a logical separation of data, applications, and security mechanisms, but in Oracle this separation is achieved using *tablespaces*.

database owner (DBO)

In Microsoft SQL Server, the user account that created the database and is responsible for managing administrative tasks related to the database.

Overview

Each SQL Server database is considered to be a self-contained administrative domain and is assigned a database owner (DBO) who is responsible for managing the permissions for the database and performing tasks such as backing up and restoring the database's information. The DBO also applies to any database object, including tables, indexes, views, functions, or stored procedures.

Essentially, the DBO can do anything within the database. By default, the SA (system administrator) account is also a DBO account for any database on a computer running SQL Server. The DBO has full permissions inside a database that it owns.

Notes

To avoid the complexity of managing separate DBO accounts for each SQL Server database, you might want to perform all administration tasks—both server-wide and specific to the database—using only the SA account.

data communications equipment (DCE)

Any device that supports data transmission over a serial telecommunications link.

Overview

Typically, data communications equipment (DCE) refers to analog and digital modems, Integrated Services Digital Network (ISDN) terminal adapters, Channel Service Units (CSU), multiplexers, and similar devices. The purpose of a DCE is to provide termination for the telecommunications link and to provide an interface for connecting data terminal equipment (DTE) to the link.

The term *DCE* specifically refers to serial transmission, which generally occurs over links such as a local loop Plain Old Telephone Service (POTS) connection, an ISDN line, or a T1 line. An example of a DCE is an analog modem, which provides a connection between a

D computer (the DTE) and the local loop POTS phone line (the serial transmission line). A DCE accepts a stream of serial data from a DTE and converts it to a form that is suitable for the particular transmission line medium being used. The DCE also works in reverse, converting data from the transmission line to a form the DTE can use.

On a Cisco router, the DCE interface is typically an RJ-45 jack on the back of the router.

Data Encryption Standard (DES)

The former U.S. government standard for encryption, now replaced by Advanced Encryption Standard (AES).

Overview

In 1972 the National Bureau of Standards called for proposals for an encryption standard to enable secure transmission of government documents by electronic means. IBM responded to the call with a 128-bit key algorithm called Lucifer, which was accepted in 1976, reduced to 56-bit key length, renamed Data Encryption Algorithm (DEA), and then further developed by the National Security Agency (NSA). In 1977, DEA was officially adopted as the Data Encryption Standard (DES) and became the official encryption standard of the U.S. government. DES is formally defined by Federal Information Processing Standard FIPS 46-1.

Implementation

DES is a symmetric encryption scheme in which both the sender and the receiver need to know the secret key in order to communicate securely. DES is based on a 56-bit key (actually a 64-bit key with 8 parity bits stripped off) that allows for approximately 7.2×10^{16} possible keys. When a message is to be encrypted using DES, one of the available keys is chosen and applied in 16 rounds of permutations and substitutions to each 64-bit block of data in the message. Because DES encrypts information 64 bits at a time, it is known as a block cipher.

Issues

DES was originally designed for hardware encryption (dedicated devices that encrypt information at high speeds). The newer AES standard is more flexible in its application, and performs well in a variety of different environments from small-footprint devices such as smart cards to ordinary desktop computers running standard operating systems.

While the large number of keys available makes DES fairly secure, it was known early on that DES was crackable in theory. In 1997, Whitfield Diffie and Martin Hellman (developers of Diffie-Hellman public key encryption) proposed a DES cracking machine that could in principle be built with existing hardware at a cost of about \$20 million. Then in 1997 a DES key was successfully cracked using the idle processing cycles of 14,000 computers cooperating over the Internet. The next year a DES cracking machine costing only \$210,000 was created by the Electronic Frontier Foundation (EFF). The EFF machine was capable of cracking a DES key in about four days. Despite these accomplishments, DES is still viewed in practice as a secure encryption algorithm because so far no other method for cracking DES keys than simple brute force (trying every possible key) has been found.

Notes

A more secure variant of DES, Triple DES, encrypts each message using three different 56-bit keys in succession. Triple DES thus extends the DES key to 168 bits in length, providing for a total of approximately 6.2×10^{57} different keys. Unfortunately Triple DES is a relatively slow encryption mechanism that is not suitable for some situations, such as cell phones having limited processing power.

Another symmetric encryption scheme is IDEA (International Data Encryption Algorithm), which uses a 128-bit key and performs 8 cipher rounds on 64 bit blocks of information. Other symmetric encryption schemes include Blowfish, CAST, RC2, RC4, and others. The most common examples of asymmetric encryption schemes are Diffie-Hellman and Rivest-Shamir-Adleman encryption (RSA).

datagram

A term sometimes used as a synonym for packet, but most often meaning a packet that is sent across a network using connectionless services, where the delivery does not depend on the maintenance of specific connections between computers.

Overview

Networking protocol suites such as Transmission Control Protocol/Internet Protocol (TCP/IP) generally support both connection-oriented and connectionless delivery services. In TCP/IP, the Transmission Control Protocol (TCP) is responsible for providing connection-oriented services that guarantee delivery of Internet Protocol (IP) packets. On the other hand, the User Datagram Protocol (UDP) handles connectionless services that guarantee only “best-effort” delivery of datagrams. For networking services that use connectionless datagrams, higher-layer protocols must ensure delivery. Datagrams are generally small packets sent over the network to perform functions such as announcements.

See Also: *connectionless protocol, connection-oriented protocol, packet, Transmission Control Protocol/Internet Protocol (TCP/IP), User Datagram Protocol (UDP)*

data integrity

The correctness and consistency of data stored in a database.

Overview

Maintaining integrity is essential, because a database is only useful if its contents can be retrieved and manipulated as expected. For example, without data integrity, data could be input into the system and then be inaccessible. Data integrity must be enforced on the database server. The following items are among those that should be verified:

- Individual field contents during insertion, updating, or deletion of data
- The values of one field relative to another (especially for primary keys) and of data in one table relative to another (especially for foreign keys)
- Successful completion of database transactions

Database systems employ many features to ensure data integrity. For example, Microsoft SQL Server 7 makes use of data types, constraints, rules, defaults, declarative referential integrity (DRI), stored procedures, and triggers. All these play a role in keeping the integrity of the database intact.

data isolator

A device that protects serial equipment from voltage surges.

Overview

If two pieces of data terminal equipment (DTE) are connected by a long serial line, voltage differences with respect to ground between the devices can cause surges over the line that can damage the devices. This can be a problem in a mainframe environment when you connect terminals to asynchronous mainframe hosts using long RS-232 cables. The problem is especially troublesome when the cabling has to run outdoors between buildings or when nearby generators or other equipment induce voltages.

Data isolator. Using a data isolator.

The solution to these problems is to insert a data isolator between the mainframe host and the terminal. This isolator provides electrical isolation between the two devices, somewhat like an opto isolator for fiber-optic cabling. Data isolators typically use transformers to electrically isolate the two connected circuits from voltage surges. Data isolators can support high data transfer speeds, and they come with a variety of interfaces, such as RS-232, RS-422, and Time to Live (TTL) connections.

data line protector

A device that provides surge protection for network cables carrying data.

Overview

Data line protectors prevent voltage spikes and surges from damaging costly hubs, switches, routers, and other devices. They are essentially surge protectors that are placed inline between stations on the network and concentrating hubs or other devices in the wiring closet. Data line protectors are available from different vendors for virtually every kind of networking connection, including RJ-45 connections for Ethernet networks, RJ-11 connections for telephone lines, and RS-232 connections for serial lines.

You connect a data line protector directly to one of the two connected devices, and then you attach the ground wire to a good ground connection so that there will be a path for voltage surges to flow down. For Ethernet networks using unshielded twisted-pair (UTP) cabling, data line protectors are available with multiple ports that are attached directly to the hub or the switch. Additional 10BaseT surge protectors can also be installed directly on the stations on the network for more protection.

Data line protector. Using a data line protector.

Notes

Most newer hubs, switches, routers, and other networking devices include built-in data line protection circuitry, which eliminates the need for additional data line protectors.

Data Link Control (DLC)

Generally, the services that the data-link layer of the Open Systems Interconnection (OSI) reference model provides to adjacent layers of the OSI protocol stack. Specifically, Data Link Control (DLC) is a specialized network protocol.

Overview

The DLC protocol is used primarily for two purposes:

- To provide connectivity with IBM mainframe or AS/400 environments, such as Systems Network Architecture (SNA), which are configured to run

DLC. DLC complements SNA because SNA operates only at higher levels of the OSI model.

- To provide connectivity for network print devices (such as certain Hewlett-Packard printers that have their own network cards and are connected directly to the network).

DLC is not used as a network protocol in the usual sense of enabling communication among computers on the network. It is not used by the redirector by the Microsoft Windows 2000 operating system and so cannot be used for session-level communication over a network. DLC is not routable; it is designed only to give devices direct access to the data-link layer. DLC is supported by most Windows operating systems, including Windows 95, Windows 98, Windows Millennium Edition (Me), Windows NT, and Windows 2000. DLC is no longer supported on Windows XP and Windows .NET Server. Windows 95 OSR2 includes both a 16-bit and a 32-bit version of DLC.

Implementation

To use DLC on Windows 2000 to connect to a Hewlett-Packard network print device, perform the following steps:

- 1 Connect the printer to the network, and run the self-test routine to obtain the printer's MAC address. Also, think of a friendly name for the printer.
- 2 Install the DLC protocol on the Windows NT or Windows 2000 server that will be used as a print server for the network print device. (Use the Network utility or the Windows 2000 Network and Dial-Up Connections utility in Control Panel.)
- 3 Run the Add Printer Wizard on the print server, choosing My Computer, Add Port, Hewlett-Packard Network Port, and New Port. Enter the friendly name for the printer, and select its MAC address from the list (or type it if the print device is offline). In Windows 2000, run the Add Printer Wizard, then right-click on the printer in the Printers folder and choose Properties. In the Property sheet for the printer, click the Ports tab, click Add Port, select Hewlett-Packard Network Port, and

then click New Port. Enter the friendly name for the printer and select its MAC address from the list (or type it if the print device is offline).

data-link layer

Layer 2 of the Open Systems Interconnection (OSI) reference model.

Overview

The data-link layer converts frames of data into raw bits for the physical layer and is responsible for framing, flow control, error correction, and retransmission of frames. media access control (MAC) addresses are used at this layer, and bridges and network interface cards (NICs) operate at this layer.

Data-link layer. Two sub-layers of the data link layer.

The data-link layer establishes and maintains the data link for the network layer above it. It ensures that data is transferred reliably between two stations on the network. It is responsible for packaging data from higher levels into frames, which are basically constructs containing data, a header, and a trailer.

Uses

A variety of network protocols can be implemented at the data-link layer. These differ depending on whether you are establishing local area network (LAN) or wide area network (WAN) connections between stations. Data-link protocols are responsible for functions such as addressing, frame delimiting and sequencing, error detection and recovery, and flow control.

Examples of data-link protocols for local area networking include the following:

- IEEE 802.3, which provides the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) access method for baseband Ethernet networks

- IEEE 802.5, which provides the token-passing access method for baseband token ring implementations

For WANs, data-link layer protocols encapsulate LAN traffic into frames suitable for transmission over WAN links. Common data-link encapsulation methods for WAN transmission include the following:

- Point-to-point technologies such as Point-to-Point Protocol (PPP) and High-level Data Link Control (HDLC) protocol
- Multipoint technologies such as frame relay, Asynchronous Transfer Mode (ATM), Switched Multi-megabit Data Services (SMDS), and X.25

Implementation

For LANs, the Project 802 standards of the Institute of Electrical and Electronics Engineers (IEEE) separate the data-link layer into two sublayers. The reason for doing this is to make it simpler for network equipment vendors to develop drivers for data-link layer services. The two sublayers of the data-link layer are the following:

- **Logical link control (LLC) layer:** This is the upper of the two layers, which is responsible for flow control, error correction, and resequencing functions for connection-oriented communication, but which also supports connectionless communication. Programming of the LLC layer is generally done by software vendors.
- **Media access control (MAC) layer:** This is the lower of the two layers, which is responsible for providing a method for stations to gain access to the medium. Programming of the MAC layer is generally done by manufacturers of network cards and similar devices.

Data Manipulation Language (DML)

A subset of Structured Query Language (SQL).

Overview

Generally speaking, the term *Data Manipulation Language (DML)* can apply to any nonprocedural

computer language designed specifically for the manipulation of structured data. In common use, DML refers to a subset of SQL commands used specifically for manipulating data in a database. The four SQL commands that comprise DML are

- **SELECT:** Lets you retrieve rows from tables
- **INSERT:** Lets you add rows to tables
- **DELETE:** Lets you remove rows from tables
- **UPDATE:** Lets you modify rows in tables

Data Over Cable Interface Specification (DOCSIS)

A specification defining standards for implementation of cable modem systems.

Overview

Data Over Cable Interface Specification (DOCSIS) is a set of standards developed by CableLabs together with a consortium of cable system vendors and operators to promote interoperability between different cable modem systems. The DOCSIS standards focus on the interaction between equipment at cable providers and their customers.

DOCSIS is also a certification issued by CableLabs to cable modem system vendors meeting DOCSIS specifications and requirements. CableLabs is responsible for certifying DOCSIS-compliant cable modems and related equipment.

Architecture

In its original and widely implemented version, DOCSIS 1 provides a specification for transmission of a single stream of data from a Cable Modem Termination System (CMTS) router at the provider, through a distribution system of more routers, to a cable modem at the customer premises. The cable modem data stream defined by DOCSIS is a best-effort shared-media system that uses contention on upstream traffic and has limited support for class of service (CoS) differentiation between different types of traffic. DOCSIS defines the physical and data-link layers for cable modem systems and solves the problem of eavesdropping due to the shared nature of the network by supporting 56-bit Data Encryption Standard (DES) encryptions of all cable modem traffic.

Data Over Cable Interface Specification (DOCSIS). How DOCSIS works.

DOCSIS 1 specifies the characteristics of upstream and downstream transmission as follows:

- **Downstream:** Data rates of 27 to 36 megabits per second (Mbps) using frequencies between 50 and 750 megahertz (MHz)
- **Upstream:** Data rates of 320 kilobits per second (Kbps) and 10 Mbps using frequencies between 5 and 42 MHz

A newer version of the specification, DOCSIS 1.1, has a number of enhancements over the original DOCSIS standard, specifically

- **Multiple data streams:** DOCSIS 1.1 supports creating multiple data streams from CMTS to customer premises. Each application can be assigned

its own data stream and priority using multiprotocol label switching (MPLS) or Diffserv, and providers can assign service level agreements (SLAs) to business customers to guarantee bandwidth for each stream.

- **Classification of traffic:** Different forms of traffic can now be mapped to specific service flows according to their content. Thus a specific Web application could be assigned a specific service flow to ensure adequate class of service for that application. Service flows themselves can be pre-configured or can be dynamically established and torn down.
- **Network access:** Access to the network can be scheduled using several different schemes including real-time polling, non-real-time polling, and constant bit rate (CBR). This provides better performance for applications that perform poorly on the simple, contention-based shared network defined in DOCSIS 1.
- **Packet fragmentation:** Large packets can be fragmented to provide better quality of service (QoS) for applications such as Voice over IP (VoIP) that require low latency.

Data Provider

A tool that simplifies data access to different kinds of data sources such as relational databases.

Overview

Also known as the OLE DB Provider for AS/400 and Virtual Storage Access Method (VSAM), Data Provider is included with Microsoft SNA Server version 4. It gives Web applications written with Microsoft Active Server Pages (ASP) technology the ability to access record-level mainframe AS/400 and VSAM file systems.

Using Data Provider, you can write applications that access legacy file data on mainframes and minicomputers running Systems Network Architecture (SNA). You can also directly access AS/400 file structures and

VSAM data sets using the IBM DDM protocol native to many IBM host systems without needing to install additional Microsoft software on the host system. You can also integrate unstructured legacy file data on host systems with data stored in a Microsoft Windows 2000 networking environment.

Data Service Unit (DSU)

A digital communication device that works with a Channel Service Unit (CSU) to connect a local area network (LAN) to a telecommunications carrier service.

Overview

Data Service Units (DSUs) provide a modem-like interface between data terminal equipment (DTE) such as a router and the CSU connected to the digital service line. DSUs also serve to electrically isolate the telco's digital telecommunication line from the networking equipment at the customer premises. While the CSU connects to the termination point of the carrier's digital line at the customer premises, the DSU connects to the access device (typically a router) at the border of the customer's LAN.

Data Service Unit (DSU). Using a DSU.

Implementation

As an example, in T1 transmission technologies, the DSU converts network data frames that are received from the router's RS-232, RS-449, or V.35 serial transmission interface into the standard DSX framing format, encoding scheme, and voltages of the T1 line. The DSU also converts the unipolar networking signal into a bipolar signal suitable for transmission over the digital line. The DSU is also responsible for handling signal regeneration and for controlling timing errors for transmission over the T1 line. DSUs usually provide other functions such as line conditioning of the T1 line, as well as remote diagnostic capabilities such as Simple Network Management Protocol (SNMP), which allows the telco central office (CO) to monitor the state of the line at the customer premises.

Notes

DSUs are usually integrated with CSUs to create a single device called a CSU/DSU (Channel Service Unit/Data Service Unit). If these devices are separate, the telco usually supplies and configures the CSU, while the customer supplies the DSU. If the devices are combined, the telco usually supplies, configures, and maintains the CSU/DSU for the customer premises.

The DSUs (or CSU/DSUs) at either end of a digital data transmission line should be from the same manufacturer. If they are not, they might not communicate with each other correctly because different vendors employ different multiplexing and diagnostic technologies that are often incompatible with those of other vendors.

data source name (DSN)

A unique name used to create a data connection to a database using open database connectivity (ODBC).

Overview

Data source names (DSNs) are used by applications that need to access or manage data in its associated database. All ODBC connections require that a DSN be configured to support the connection. When a client application wants to access an ODBC-compliant database, it references the database using the DSN.

Data source name (DSN). Configuring a DSN.

You can configure a DSN for an ODBC-compliant database using the Microsoft Windows 2000, Windows XP, or Windows .NET Server Administrative Tools\Data Sources (ODBC) utility in Control Panel. You can create three kinds of DSNs:

- **User DSN:** This is visible only to the user who creates it and can be used only on the current machine.
- **System DSN:** This is visible to all users on the machine and is also accessible to Windows NT, Windows 2000, Windows XP, or Windows .NET Server services. A system DSN is stored in the registry.
- **File DSN:** This can be shared by users who have the same ODBC drivers installed. A file DSN is stored in a file.

Notes

When you design Web applications that use Microsoft ActiveX Data Objects (ADO) for accessing database information, be sure to use either a file DSN or a system DSN because ADO does not work with user DSNs.

Data Space Transfer Protocol (DSTP)

A protocol for accessing large amounts of information stored in distributed locations.

Overview

The Data Space Transfer Protocol (DSTP) is a new protocol designed to transport gigabits of information at high speeds around the globe. DSTP finds typical applications in international research projects between different universities where large amounts of data are generated and need to be shared and analyzed. Typical applications include human genome analysis and particle physics.

Implementation

DSTP is derived from Network News Transfer Protocol (NNTP) and uses a similar stream architecture augmented by a command set similar to Simple Mail Transfer Protocol (SMTP). DSTP enables information stored in different formats on servers in different locations to be indexed and retrieved in the form of a database file consisting of rows and columns. Indexing and retrieval is facilitated using a key called a Universal Correlation Key (UCK), which is used to create an Extensible Markup Language (XML) index file by tagging columns in databases.

DSTP is capable of transferring multiple flat-file databases simultaneously at high speeds.

data tap

A type of networking device that you can use to monitor the flow of data in serial lines.

Overview

Data taps provide an easy way to connect monitoring equipment such as data scopes to serial interfaces such as RS-232. These serial connections are used for a variety of networking purposes, including connecting data terminal equipment (DTE) such as servers and routers to data communications equipment (DCE), such as modems, and CSU/DSUs (Channel Service Unit/Data Service Units) for implementing wide area networks (WANs); connecting dumb terminals to asynchronous

mainframe hosts; and connecting servers to plotters and other serial devices. Data taps generally display network traffic in binary, hexadecimal, or character format and are used for troubleshooting various kinds of network connections.

D

Data tap. Using a data tap to troubleshoot a serial connection.

A data tap is essentially a three-way connector in which the third connector interfaces with the test equipment. For RS-232 serial lines, data taps come in a variety of configurations, with mixtures of male and female DB-9 and DB-25 connectors.

data terminal equipment (DTE)

Any device that is a source of data transmission over a serial telecommunications link.

Overview

The term *data terminal equipment (DTE)* specifically refers to a device that uses serial transmission such as the transmissions involving the serial port of a computer. Most serial interface devices contain a chip called a universal asynchronous receiver-transmitter (UART) that can translate the synchronous parallel data transmission that occurs within the computer's system bus into an asynchronous serial transmission for communication through the serial port. The UART also performs other functions in a DTE, including the following:

- **Error detection:** Ensures that data arrives at its destination uncorrupted
- **Clocking:** Ensures that data is sent at the correct rate in order to be received at its destination

Typically, data terminal equipment (DTE) can be a computer, a terminal, a router, an access server, or some similar device. The earliest form of DTE was the teletype machine.

Implementation

To connect a DTE to a telecommunications link, you use data communications equipment (DCE). The DCE provides termination for the telecommunications link and an interface for connecting the DTE to the link. In other words, the DCE connects to the carrier's phone line and the DTE connects to the customer's network or system. The DTE and DCE are then joined together using a serial cable. Typical serial interfaces for DCE-to-DTE connections include RS-232, RS-449, RS-530, X.21, V.35, and HSSI.

An example of a DCE would be an analog modem, which can be used for connecting a DTE such as the serial port on a computer or router to the local loop connection of the Plain Old Telephone Service (POTS).

Data terminal equipment (DTE). Example of DTE.

While the usual configuration is to connect DTE with DCE, there are situations where DTE may need to be connected to DTE, for example when a computer needs to be connected to a router using a serial interface. In this situation a null modem cable is required.

DB connector

A common family of connectors used for connecting data terminal equipment (DTE).

Overview

The letters *DB* stand for *data bus* and are followed by a number that indicates the number of lines or pins in the connector. DB connectors were formerly called D-series connectors. DB connectors can be used for either serial or parallel connections between devices.

Common members of the DB family include the following:

- **DB-9:** A 9-pin serial connector for connecting modems, serial printers, mouse devices, and so on

- **DB-15:** A 15-pin connector for connecting such devices as Macintosh monitors and network interface cards (NICs) for 10Base5 drop cables
- **DB-25:** A 25-pin connector for connecting Macintosh Small Computer System Interface (SCSI) devices, modems, serial printers, parallel cables, and switch boxes, among other equipment
- **DB-37:** A 37-pin connector for connecting such devices as routers and Channel Service Units (CSUs)
- **DB-60:** A 60-pin connector for connecting such devices as Cisco routers

D channel

One of two channels used in Integrated Services Digital Network (ISDN).

Overview

An ISDN D-channel is a circuit-switched channel that carries signaling information between the customer premises termination and the central office (CO) of the telecommunications service provider, or telco. The letter *D* here stands for *data* or *delta*. The D channel is used to signal the telco CO when connections need to be created or terminated. The D channel is thus a control channel for ISDN call setup and tear down.

Customer premises

D channel. How the D channel works.

The D channel forms the “D” part of a 2B+D Basic Rate Interface ISDN (BRI-ISDN) line and carries signaling information at a rate of 16 kilobits per second (Kbps). On a 23B+D Primary Rate Interface ISDN (PRI-ISDN) line, the D channel carries signaling information at the faster rate of 64 Kbps.

Implementation

D channel communication uses a completely separate out-of-band communication network called the Signaling System 7 (SS7) network, as shown in the illustration.

This telco network is dedicated solely to servicing system functions that are overhead as far as voice or data communication is concerned. The SS7 network on which D channel communication takes place makes possible the low latency of dial-up ISDN connections, which are typically 1 or 2 seconds (compared to a latency of 15 to 30 seconds for analog phone connections).

The data-link layer of the D channel is defined by the Q.921 standard and uses LAPD (Link Access Protocol, D-channel) for full-duplex, synchronous, serial communications. The physical layer of the D channel is no different from that of the B channel.

Notes

In ISDN voice communication, D channels are also used to activate special calling features such as line call forwarding and caller ID.

See: *Distributed Component Object Model (DCOM)*

DCOM Configuration Tool

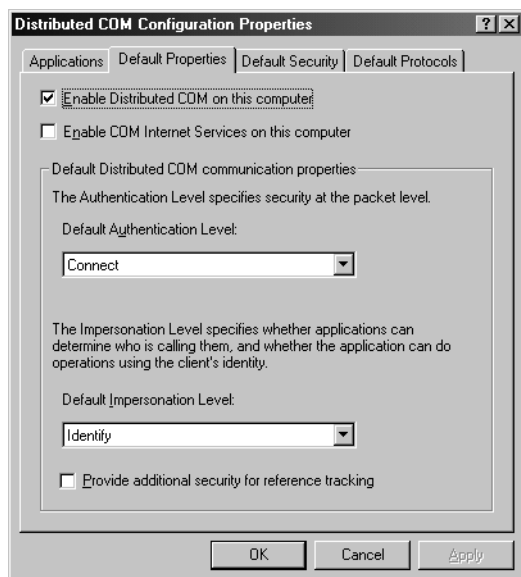

A Microsoft Windows NT, Windows 2000, Windows XP, Windows .NET Server, and Windows 98 utility used to configure 32-bit Windows applications for Distributed Component Object Model (DCOM) communication between components of distributed applications on a network.

Overview

You can use the DCOM Configuration Tool to configure DCOM applications to run across computers on a network. Computers can be configured to operate as DCOM clients (making calls to DCOM servers), DCOM servers, or both. Using this tool, you can configure the locations of components of distributed applications and the security settings for those components.

Implementation

To start the tool, choose Run from the Start menu, and then type **dcomcnfg**. To use the tool to configure a distributed application, you must specify the security and location properties of both the calling client application and the responding server application. For the client application, you specify the location of the server application that will be called by the client. For the server application, you select a user account that will have permission to start the application and the user accounts that will run it.

dead spot

In wireless networking, a location within the coverage area where a signal is not received.

Overview

Dead spots are typically caused by physical barriers (such as buildings or concrete structures) that absorb or reflect radio or microwave frequencies. The receiving station

D must relocate or the barrier must be moved if the station is to receive a signal. Dead spots can also be caused by high levels of electromagnetic interference (EMI) from heavy machinery (such as motors and generators) or broad-spectrum sources of radiation (such as microwave ovens). In these cases, too, the solution is to relocate the receiver or eliminate the source of interference.

decibel

A mathematical way of representing power ratios.

Overview

A decibel (dB) is the ratio of two values that measure signal strength, such as voltage, current, or power. This ratio is expressed using base 10 logarithms. In mathematical terms, this means that the decibel is defined as follows, where P1 and P2 are the power (signal strength) measurements:

$$\text{dB} = 10 \log_{10} (P1/P2)$$

Uses

In computer networking and telecommunications, decibels are the units used for measuring signal loss within a circuit. Decibels are also used in network cabling systems for measuring signal losses. In addition, quantities such as attenuation and near-end crosstalk (NEXT) for fiber-optic cabling are expressed in units that contain decibels. In this scenario, P1 is the strength of the signal when it enters the cabling system, and P2 is its strength at some later point, after it has traversed segments of cable, repeaters, connectors, and other cabling system components. The following table shows signal strength ratios expressed both as ratios and as decibels for conversion purposes.

Signal Strength Ratios

<i>Signal Strength Ratio (P1:P2)</i>	<i>Decibels (dB)</i>
1:1 (no signal loss)	0 dB
2:1 (50 percent signal loss)	-3 dB
4:1 (75 percent signal loss)	-6 dB
10:1 (90 percent signal loss)	-10 dB
100:1 (99 percent signal loss)	-20 dB
1000:1 (99.9 percent signal loss)	-30 dB

Notes

The Category 5 (Cat5) cabling version of unshielded twisted-pair (UTP) cabling has an attenuation rating of 30 dB/1000 feet. This means that after traveling 1000 feet (304 meters) along a UTP cable, the electrical strength of the signal typically diminishes by 99.9 percent and is only 0.1 percent of its original strength at the far end of the cable.

DECnet

A protocol suite developed by Digital Equipment Corporation (DEC).

Overview

DECnet was originally designed in 1975 to allow PDP-11 minicomputers to communicate with each other. DECnet conforms to the Digital Network Architecture (DNA) developed by DEC, which maps to the seven-layer Open Systems Interconnection (OSI) reference model for networking protocols.

OSI Layer	Digital Network Architecture (DNA)		
7	Network applications		Network management
6			
5	Session		
4	End-to-end communication		
3	Routing		
2	Ethernet	Token Ring	FDDI ...
1			

DECnet. Overview of DECnet.

DECnet is essentially a peer-to-peer networking protocol for all DEC networking environments. DECnet supports various media and link-layer technologies, including Ethernet, Token Ring, and Fiber Distributed

Data Interface (FDDI). The current release of DECnet is called Phase V, but DECnet is essentially a legacy protocol that is rarely used nowadays.

dedicated line

Any telecommunications line that is continuously available for the subscriber with little or no latency.

Overview

Dedicated lines are also referred to as leased lines, since businesses lease these lines from telcos so that they can have continuous, uninterrupted communication with branch offices and with the Internet. The opposite of a dedicated line is a dial-up line, which costs less because it is used intermittently and requires fewer telco resources. However, dial-up lines suffer from the delaying effects of latency as well as less available bandwidth. Dial-up lines are generally local loop Plain Old Telephone Service (POTS) connections that use modems and provide backup services for more expensive leased lines. Dedicated lines, on the other hand, use specially conditioned phone lines and are allocated to the subscriber's private domain with dedicated switching circuits. By contrast, circuits for dial-up lines are shared with all other subscribers in the Public Switched Telephone Network (PSTN) domain.

Dedicated lines can be either point-to-point or multipoint communication paths. They are generally synchronous digital communication lines, and are terminated with one of the following serial interfaces: RS-232, RS-449, RS-530, X.21, V.35, or HSSI.

Advantages and Disadvantages

The main advantages of dedicated lines are the following:

- They involve minimal connection delays and minimal latency for establishing communication.
- They provide a consistent level of service.
- They are always available without any busy signals.

The main disadvantage of dedicated lines is that they cost more than dial-up lines.

Dedicated Token Ring (DTR)

A high-speed Token Ring networking technology.

Overview

Dedicated Token Ring (DTR) is an extension of 802.5 Token Ring technologies developed as an evolutionary upgrade to higher speeds for Token Ring users. It defines a set of signaling protocols and topologies that are backward-compatible with standard Token Ring networking.

DTR uses the same 802.5 frame format as standard Token Ring and supports full-duplex communications using the Transmit Intermediate (TXI) protocol to allow simultaneous transmission and reception of frames by stations.

DTR uses special concentrators to create high-speed ring topology networks. A traditional Token Ring Multistation Access Unit (MAU) can be joined to a DTR concentrator to enable 802.5 stations to communicate over the high-speed ring.

Prospects

Although DTR began development in 1995, it has fallen into eclipse in recent years along with standard Token Ring technologies due to the continued evolution of Ethernet into its Fast Ethernet and Gigabit Ethernet (GbE) varieties.

default gateway

An address in a routing table to which packets are forwarded when there is no specific route for forwarding them to their destination.

Overview

In an internetwork, a given subnet might have several router interfaces that connect it to other, remote subnets. One of these router interfaces is usually selected as the default gateway of the local subnet. When a host on the network wants to send a packet to a destination subnet, it consults its internal routing table to determine whether it knows which router to forward the

packet to in order to have it reach the destination subnet. If the routing table does not contain any routing information about the destination subnet, the packet is forwarded to the default gateway (one of the routers with an interface on the local subnet). The host assumes that the default gateway knows what to do with any packets that the host itself does not know how to forward.

Default gateway. How a default gateway works.

When configuring a client machine on a TCP/IP internetwork, the client must know the Internet Protocol (IP) address of the default gateway for its network. On Microsoft Windows NT, Windows 95, and Windows 98 clients, you configure this information on the TCP/IP property sheet for the client. The property to configure is known as the Default Gateway Address. In Windows 2000, Windows XP, and Windows .NET Server, you can have a default gateway assigned automatically using Dynamic Host Configuration Protocol (DHCP).

Defense Messaging System (DMS)

A global messaging system for the U.S. Department of Defense (DoD).

Overview

The Defense Messaging System (DMS) is a program established by the U.S. Undersecretary of Defense (Acquisition) to develop an integrated, global messaging system for transferring classified and unclassified data. The Defense Messaging System (DMS) will replace the existing Automatic Digital Network (AUTODIN) system currently in use by the U.S. Department of Defense.

Microsoft Exchange DMS, a version of Microsoft Exchange Server, complies with the DMS specification. It is suited for government agencies that are required to use DMS-compliant products and for companies that do defense business with the U.S. government. Exchange DMS technology can be purchased only through Lockheed Martin Federal Systems.

defragmentation

The process of reorganizing information written on disk drives to make reading the information more efficient.

Overview

When files on disk drives are frequently written, copied, moved, and deleted, the information stored on the drive tends to become fragmented over time. Instead of storing a file across several contiguous (successive) sectors of the drive, files tend to become split up into discontinuous (disconnected) portions scattered all over the drive. Then when the file needs to be accessed again, the drive heads need to skip around a lot to find and read the successive portions of the file, which is a slower process than if the file was located in only one continuous section of the drive. Fragmented drives thus perform more poorly for disk reads (and writes) than drives that are not significantly fragmented. And the more often files are modified on a drive, the more fragmented it tends to become and the more poorly it performs (you

can hear the sound of a fragmented drive “thrashing” as it reads files while loading programs and data into memory).

To improve performance of a fragmented drive, the drive should be defragmented. A defragmentation tool is an application that reads portions of fragmented files, copies them to memory, erases them from the disk, and then copies them back to the disk in successive sectors or clusters for better performance. Defragmentation can be performed on files, free space, or both for best performance, and should be done regularly on all computers and particularly those (such as file servers) that experience a lot of disk reads and writes.

Marketplace

Studies by industry analysts have estimated that as much as \$50 billion per year is being lost by businesses simply by failing to defragment computers regularly on their networks. While best gains are achieved by defragmenting servers regularly (performance gains of 10 percent to 20 percent are typical), workstations also perform better when periodically defragmented. In spite of these estimates, the present penetration of network defragmentation software in enterprise environments is currently less than 15 percent, so much work remains to be done alerting IT (information technology) administrators to the problem.

While Windows 2000 and other operating systems have their own built-in defragmentation tools, several third-party vendors offer defragmentation tools that are more powerful and manageable and allow an administrator to centrally configure and schedule defragmentation of computers across a network. Some of the more popular tools include Diskeeper from Executive Software (Windows 2000 includes a “light” version of this tool that lacks scheduling capability), PerfectDisk from Raxco Software, and Norton Speed Disk from Symantec Corporation.

delegation

A feature of Microsoft Windows 2000 and the Windows .NET Server family that simplifies the administration of Active Directory directory service.

Overview

Delegation is a process for simplifying the assignment of permissions and rights to an object, container, or subtree of containers or organizational units (OUs) within Active Directory. These permissions and rights can be assigned for the following purposes:

- Delegating management of a portion of Active Directory to a user or group of users by assigning permissions or rights to a portion of Active Directory
- Protecting a portion of Active Directory from unauthorized access by denying permissions or rights to a portion of Active Directory

Using delegation, the network administrator can distribute the job of managing an Active Directory enterprise-level implementation among a group of individuals, each with the appropriate permissions and rights to manage her or his portion of the directory. For example, users can be granted permissions and rights on the Users container so that they can create new users or modify the attributes of existing ones. In this fashion, the network administrator can be relieved of the tiresome duty of creating and configuring new user accounts by delegating the job to a junior administrator. Delegation is designed to relieve the network administrator of the burden of managing the entire Active Directory and is an important security management feature in Windows 2000 and Windows .NET Server.

You can perform delegation using the Delegation of Control Wizard, which is part of the Active Directory Users and Computers administrative tool, and you can use it to delegate administration of portions of Active Directory to other administrators and users.

Delegation is part of the security framework of Active Directory. Along with other features such as the discretionary access control list (DACL), inheritance, and trust relationships, it enables Active Directory to be administered securely, protected from unauthorized access.

Notes

Always delegate administrative control at the level of OUs, not at the level of individual objects. This allows you to better manage access to Active Directory because OUs are used to organize objects in the directory. One good idea is to delegate authority to those who are responsible for creating users, groups, computers, and other objects that commonly change in an enterprise.

Always assign permissions to groups instead of to individual users. Groups can be nested within one another and, together with inheritance of permissions, they provide a powerful tool for organizing the administration of Active Directory.

Delegation of Control Wizard

A wizard that you can run using the Active Directory Users and Computers administrative tool for networks in Microsoft Windows 2000 and the Windows .NET Server family.

Overview

The Delegation of Control Wizard facilitates delegating control of different portions of Active Directory directory service to other administrators and users. The wizard simplifies the process by allowing only the administrator to assign permissions at the level of organizational units (OUs). Assigning permissions to OUs rather than to particular directory objects ultimately simplifies the Active Directory administrator's work.

To start the wizard, open the Active Directory Users and Computers tool, select the OU for which you want to delegate control, and on the Action menu, choose Delegate Control. Specify the users or groups to whom you want to delegate control, the subset of object types in the OU for which this should take place, and the kinds of permissions you want to assign.

Demand-Dial Routing (DDR)

A method for forwarding packets on request across a Point-to-Point Protocol (PPP) wide area network (WAN) link.

Overview

Demand-Dial Routing (DDR) is a technology in Microsoft Windows 2000 and the Windows .NET Server family that uses PPP links to create on-demand connections for transferring packets to remote networks. DDR works with a variety of dial-up technologies, including Public Switched Telephone Network (PSTN), Integrated Services Digital Network (ISDN), and X.25.

DDR is used to connect networks and uses Windows 2000 and Windows .NET Server's Routing and Remote Access Service (RRAS). DDR links are represented by RRAS as demand-dial interfaces and can be either persistent or on-demand and either one-way or two-way initiated. DDR is different from remote access—in remote access a single user connects to a remote network, but in DDR two networks connect. Like remote access connections, however, DDR connections can use the same security and encryption mechanisms, be implemented using remote access policies, support Remote Authentication Dial-In User Service (RADIUS) authentication, and use advanced PPP features such as Multilink PPP (MPPP), Microsoft Point-to-Point Compression (MPPC), and Bandwidth Allocation Protocol (BAP).

Notes

Demand-Dial Routing (DDR) is not the same as Dial-on Demand Routing (DDR), a Cisco router technology for connectivity-on-demand between Cisco routers.

demand priority

The media access control method used by 100VG-AnyLan networks.

Overview

100VG-AnyLan is a high-speed networking architecture developed by Hewlett-Packard and based on the Institute of Electrical and Electronics Engineers (IEEE) standard 802.12. Demand priority is the method by which stations on a 100VG-AnyLan network gain access to the wire for transmitting data.

Implementation

A 100VG-AnyLan network based on the demand priority access method consists of end nodes (stations), repeaters (hubs), switches, routers, bridges, and other networking devices. A typical 100VG-AnyLan network consists of a number of stations plugged into a cascading star topology of repeaters (hubs). Because of timing, a maximum of five levels of cascading of the physical wiring is permitted. Hubs are connected using uplink ports. Each hub is aware only of the stations directly connected to it and any hubs that are uplinked from it.

Demand priority. How the demand priority media access method works.

The key feature of the demand priority access method, as shown on the illustration, is that the 100VG-AnyLan hubs control which computers are allowed to transmit signals on the network at any given moment. Hubs can be thought of as servers and end nodes as computers (clients). With demand priority, a client (a computer with a 100VG-AnyLan network interface card installed

in it) must first request access to the network media (cabling) before transmitting data. The server (hub) processes this request and decides whether to allow the client access to the media. If the hub decides to grant the client access to the wire, it sends the client a signal informing it of this decision. The client then takes over control of the media and transmits its data.

Demand priority is considered a contention method, but it operates differently from the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) access method used in Ethernet networks. Cables in a 100VG-AnyLan network are capable of transmitting and receiving data at the same time using all four pairs of twisted-pair cabling in a quartet signaling method. Each pair of wires in a twisted-pair cable transmits and receives data at 25 megahertz (MHz), for a total bandwidth of 100 MHz. All contention on the network occurs at the hub. If two computers attempt to transmit signals at the same time, the hubs can either choose between the two signals based on priority or alternate between them if the priorities are equal. The hubs can do this because demand priority provides mechanisms for prioritizing transmission of different data types. Computers in demand priority networks can simultaneously transmit and receive data, and they do not need to listen to the network because the hubs control access to the wire.

demarc

The point in a carrier's wide area network (WAN) service at which the customer's responsibility for line management ends and the carrier's responsibility begins.

Overview

Demarc is short for *demarcation point* and indicates the point at which the carrier assumes responsibility for troubleshooting the WAN connection. For example, if a carrier provides the customer with a Channel Service Unit/Data Service Unit (CSU/DSU) for a leased line, the CSU/DSU is included within the carrier's

D

D responsibility and the demarc point is the serial interface on the CSU/DSU to which the customer's router is connected. If the demarc point instead is the RJ-48 connector that terminates the leased line at the customer premises, then the customer is responsible for managing and troubleshooting (and possibly also providing) the CSU/DSU that connects to this connector.

denial of service (DoS)

Any attack conducted against a system that tries to prevent legitimate users from accessing it.

Overview

Denial of service (DoS) refers to a broad family of different methods that hackers use to try to prevent legitimate users from accessing Web servers, mail servers, networks, and other systems. DoS attacks exploit weaknesses inherent in the Transmission Control Protocol/Internet Protocol (TCP/IP) suite, bugs in operating systems and applications, and holes in firewalls and other security devices. Over the last half dozen years, holes have been discovered in Apache, Berkeley Internet Name Domain (BIND), Sendmail, Internet Information Services (IIS), Common Gateway Interface (CGI), Simple Network Management Protocol (SNMP), and other systems that make them vulnerable to DoS attacks. Vendors of these systems have issued patches to guard against these attacks, but new ones are often being discovered.

Generally speaking, DoS attacks occur when a malicious user consumes so many resources on a remote network or system that none are left for legitimate users who need them. The resources attacked might include processors, disk space, memory, network connections, modems, and telephone lines. In a way, a DoS attack is like driving an extra-wide truck down a freeway—the truck blocks legitimate traffic from getting through to its destination.

Another general goal of DoS attacks is to disable critical services on a machine. Once these services are disabled, requests from legitimate users cannot be serviced until the machine is rebooted. For example, if an attacker can send malformed packets to a Web server to shut down its Hypertext Transfer Protocol (HTTP) service, the attacker has succeeded in denying access to the server by its real clients.

History

DoS attacks are not new in theory—a similar technique, jamming, was used during World War II to render enemy radar systems unusable by overwhelming them with useless information. The developers of TCP/IP envisioned the possibility of DoS attacks early on as an inevitable result of the open nature of TCP/IP, but it was not until 1996 that DoS attacks caught widespread public attention when an Internet service provider (ISP) called PANIX in New York experienced a sustained DoS attack on its servers that denied Internet services to legitimate users for more than a week. This attack demonstrated the Internet's fragility and led many vendors to patch weaknesses in their products that could be exploited by DoS attacks.

DoS again made the front page in 1999 when a number of U.S. government Web sites (including the FBI's Web site) were attacked by disgruntled hackers as retaliation for an FBI crackdown on some of their members.

More recently, a new and deadlier type of attack called Distributed Denial of Service (DDoS) made headlines in February 2000 when a young Canadian nicknamed Mafiaboy allegedly denied service for several hours to a number of major commercial Web sites, including Yahoo!, eBay, Amazon.com, Buy.com, E-Trade.com, ZDNet, and CNN.com. Also in 2000, a coordinated Distributed Denial of Service (DdoS) attack was

launched against the Internet's Internet Relay Chat (IRC) system, crippling the system for several weeks.

The Internet Engineering Task Force (IETF) is currently working on a new Internet protocol called ICMP Trace-back Messages that, if implemented widely, would allow networks experiencing DoS attacks to better determine the source of the attacks. Until then, network managers and system administrators need to be vigilant in applying the latest patches to systems and monitoring their networks for evidence of intrusion and DoS attacks.

Types

There are a number of different types of DoS attacks. Some of these are described in some detail below, but others are mentioned only briefly.

- **Synchronous idle character (SYN) flooding:** This famous attack exploits weaknesses in the three-way handshaking protocol of TCP. Typically, SYN flooding is used to render a Web server's networking services unavailable. SYN flooding is a type of attack in which TCP connection request packets (SYN packets) are sent in large numbers to a Web server. These packets use a false or "spoofed" source IP address to hide the attacker to fool the server into sending responses to a nonexistent client. SYN packets are used to place the TCP ports in the SYN_RECEIVED, or "half-open," state on the Web server and then do nothing with them until they time out. If enough of these ports are half-opened, the server cannot handle requests from normal clients until the unused ports expire. Unfortunately, it takes time for the half-opened ports to time out because when a SYN packet is received, the server generates a SYN-ACK packet to acknowledge the request and then waits for a final ACK from the requester before fully opening the port for a communication session. (This is called a TCP three-way handshake.) However, that final ACK is not received because the source address in the SYN packet was spoofed. The SYN-ACK packet is thus retransmitted several times at increasingly longer time intervals until, after a total time of 189 seconds (in the implementation of TCP/IP on Microsoft Windows platforms), the server finally gives up and closes the half-open port. For that time period, the requested port is unavailable to perform any other services.
- **Ping of Death:** This type of attack floods a machine or network with malformed Packet Internet Groper (PING) packets to crash remote systems. Many operating systems are vulnerable to this type of attack, as are some routers and network printers. Check with your vendor for any patches that have been released to deal with this type of attack. Also be sure to configure your routers not to allow broadcasts to pass into your network from outside.
- **Smurf attack:** This variant of the Ping of Death employs an intermediate network to send broadcast pings to tie up a system. A broadcast ping is an Internet Control Message Packet (ICMP) directed to a subnet broadcast address and is received by all hosts on the subnet. The source address of the broadcast ping is spoofed to appear as the address of the machine being targeted. The effect is for the targeted system to receive a flood of ICMP Echo response packets, depending on how many intermediate systems are employed. For more information, see the article "Distributed Denial of Service (DDoS)" elsewhere in this chapter.
- **Overlapping fragment attack:** This attack fragments packets into small pieces and then reassembles them starting from the middle of a packet instead of the beginning. The resulting bad packets are held in the receiving system's buffer until the system's memory resources are full, causing the machine to hang up.
- **Address Resolution Protocol (ARP) cache poisoning:** This attack preloads false information into a system's ARP cache, preventing it from communicating over the network with other systems.
- **Domain Name System (DNS) cache poisoning:** This attack fills the cache on name servers with name lookup information about nonexistent hosts, causing legitimate name lookup requests to be dropped. Upgrading to the latest version of BIND solves this problem.
- **User Datagram Protocol (UDP) attack:** This attack causes two systems to send a continuous flood of UDP packets to each other, preventing legitimate network communications from being able to occur.

- **Mail bombs:** This type of attack tries to overwhelm mail servers by sending them large amounts of useless messages. Mail filters are the usual method for dealing with such attacks.

D

Notes

If users try to connect to an IIS Web server and receive error messages such as “The connection has been reset by the remote host,” a SYN attack might be under way on your machine. (When the maximum number of TCP ports are in use [open or half-open] on a machine, the machine usually responds to any further connection attempts with a reset.)

To determine whether such an attack is in progress, type `netstat -n -p tcp` at the command prompt to see whether there are a large number of ports in the half-open SYN_RECEIVED state. If so, try using a network protocol analyzer such as Network Monitor to further examine the situation. You might need to contact your ISP to investigate the problem more closely.

If your server is under a heavy SYN attack, one fix you can try on Windows NT platforms running Microsoft IIS is to decrease the default timeout for terminating half-open TCP connections. Open the `TcpMaxConnect-ResponseRetransmissions` parameter in the registry and set it to 3, 2, or even 1 to reduce the timeout to 45, 21, or 9 seconds, respectively. However, if you set this parameter too low, legitimate connections might experience timeouts. Windows 2000 and Windows NT 4 Service Pack 3 have corrected this problem. A fix is available for Windows NT version 3.51 from Microsoft Corporation.

If your Cisco router is experiencing a SYN attack, use the TCP Intercept feature to validate incoming TCP connection requests to counter the flood.

dense mode

One of two forms of the spanning tree algorithm used in multicasting.

Overview

While sparse mode routing is designed to be efficient in routing multicast packets to clusters of hosts across a network, dense mode is intended for large-scale multicasting where hosts are spread out across every corner of the network. Dense mode thus assumes that hosts are densely concentrated in large subnets. An example of a situation where dense mode multicasting is required would be a large-scale webcast of a corporate presentation or sports event.

Implementation

Dense mode multicasting creates multiple routing trees, one for each multicast group. Dense mode multicasting floods the network with multicast packets and so assumes that a large amount of bandwidth is available for transmission. Packets are multicast to every area of the network, and then the unneeded branches of the routing tree are pruned for more efficiency.

Dense mode multicasting can employ several different routing protocols to handle the flow:

- Distance Vector Multicast Routing Protocol (DVMRP)
- Multicast Open Shortest Path First (MOSPF)
- Protocol Independent Multicast Dense Mode (PIM-DM)

dense wavelength division multiplexing (DWDM)

A multiplexing technology for achieving extremely high data rates over fiber-optic cabling.

Overview

Also known sometimes as simply wavelength division multiplexing (WDM), dense wavelength division multiplexing (DWDM) modulates multiple data channels into optical signals that have different frequencies and then multiplexes these signals into a single stream of light that is sent over a fiber-optic cable. Each optical signal has its own frequency, so up to 160 separate data streams can be transmitted simultaneously over the fiber using only eight different light wavelengths. In addition, each data stream can employ its own transmission format or protocol. This means that, using DWDM, you can combine Synchronous Optical Network (SONET), Asynchronous Transfer Mode (ATM), Transmission Control Protocol/Internet Protocol (TCP/IP), and other transmissions and send them simultaneously over a single fiber. At the other end, a multiplexer demultiplexes the signals and distributes them to their various data channels.

Dense wavelength division multiplexing (DWDM). How DWDM is implemented.

Marketplace

Many networking vendors now offer switching equipment that supports DWDM. Big players in this area include Lucent Technologies and Nortel Networks, with numerous smaller players being attracted to the market.

An example of a DWDM deployment is AT&T, which has implemented DWDM switching equipment through

much of its long-haul backbone network to carry up to 80 different channels per strand of fiber, and is planning to upgrade this soon to 160 and eventually 320 channels per fiber. This managed DWDM service from AT&T is called Ultravailable Broadband Network, and it can provide 2.4 gigabits per second (Gbps) of bandwidth for metropolitan-area connections where it is available. AT&T targets mainly large enterprises that enter into long-term contracts for these services.

Prospects

DWDM is rapidly replacing time-division multiplexing (TDM) as the standard transmission method for long-haul high-speed fiber-optic carrier links. The main deployment issue for many carriers is cost: devices that support DWDM are more expensive because the laser light sources for generating signals over fiber must be extremely stable. The benefits are so great, however, that many carriers are moving toward implementing it on their backbone networks, particularly long-distance carriers (inter-exchange carriers, or IXC's) who see the greatest benefit/cost ratio in deploying it. DWDM is less likely to be used by competitive telcos (competitive local exchange carriers or CLECs) or baby bells (regional bell operating companies, or RBOCs) for their access networks because of the cost of upgrading equipment to support DWDM compared to simply laying additional fiber to meet their needs.

A newer all-optical switching technology called lambda switching has recently evolved from DWDM and promises significant advantages over traditional DWDM. As a result of these developments, some carriers are holding back on further DWDM deployments while they wait for the new technology to mature.

desktop

The graphical user interface (GUI) for Microsoft Windows 95, Windows 98, Windows NT version 4, Windows 2000, Windows XP, and Windows .NET Server operating system platforms.

Overview

The desktop is the user's on-screen work area; its various icons and menus are arranged as if on top of a physical desk. Users can place items on the desktop, drag them around, move them into folders, and start and stop tasks using simple mouse actions such as clicking, double-clicking, dragging, and right-clicking.

When the Active Desktop feature of many of these platforms is selected, Web browser functions also appear on the desktop. Users can browse local and network file system objects along with content on the Internet using a familiar Web browser paradigm. Active Web content can be placed directly on the desktop and updated automatically.

Desktop Management Interface (DMI)

A standard for managing desktop systems developed by the Desktop Management Task Force (DMTF), now the Distributed Management Task Force.

Overview

Desktop Management Interface (DMI) was designed to allow information to be automatically collected from system components such as network interface cards (NICs), hard disks, video cards, operating systems, and applications that comply with the DMI standard. DMI was designed to be operating system-independent and protocol-independent and was designed for use on local systems that do not have a network installed.

Implementation

DMI by itself does not specify a protocol for managing systems over the network. Instead, DMI must use an existing network management protocol such as Simple Network Management Protocol (SNMP) to send and receive information over the network. DMI is in fact

similar in design to SNMP. Each component to be managed must have a Management Information Format (MIF) file that specifies the location of the component, name of vendor and model, firmware revision number, interrupt request line (IRQ), input/output (I/O) port address, and so on. MIF files are formatted as structured ASCII flat-file databases; the Desktop Management Task Force has defined several standard MIFs, including the Desktop System MIF file, the Adapter Card MIF file, and the Printer MIF file.

DMI service layer software running on the desktop collects information from DMI-enabled components and stores this information in the appropriate MIF file. The service layer thus acts as an intermediary between the DMI-enabled components and the DMI management application, and it coordinates shared access to the various MIFs installed on the desktop system. DMI management applications can then query the service layer on the desktop to obtain the various system components and applications from these MIF files. The service layer allows the management layer to interact with the MIFs by using commands such as

- **Get:** Obtains information from a MIF
- **Event:** Alerts the management application when certain events occur
- **Set:** Modifies the contents of a MIF

One advantage of DMI over SNMP is that DMI management applications can access MIF files even when they have no prior information about them.

DMI management applications include Intel Corporation's LANDesk and Microsoft Systems Management Server (SMS). SMS 1.2 uses standard DMI 4.5 MIF files to expose inventory data for systems it manages and then stores this information in a Microsoft SQL Server database.

Prospects

DMI is now considered a legacy specification, and the newer Web-Based Enterprise Management (WBEM) initiative from the DMTF has largely replaced it. WBEM specifies a Common Information Model (CIM) as a common abstraction layer for unifying the various

existing data providers for system and network management, including DMI and SNMP. Microsoft Corporation has implemented WBEM into the Windows 2000, Windows XP, and Windows .NET Server family operating systems as Windows Management Instrumentation (WMI) and in Microsoft System Management Server 2.

destination address

The address to which a frame or packet of data is sent over a network.

Overview

The destination address is used by hosts on the network to determine whether the packet or frame is intended for them or for other hosts. The destination address is also used by routers to determine how to forward the packet or frame through an internetwork. The destination address can be one of the following:

- **Physical address:** For example, the media access control (MAC) address of an Ethernet frame
- **Logical address:** For example, the Internet Protocol (IP) address of an IP packet

Destination addresses can be either specific or general. Specific addresses point to a specific host on the network. A general address points the packet or frame to all hosts on the network or multicasts it to a specific multicast group of hosts on the network.

You can see the destination address of a packet or frame by using a network sniffer device such as Network Monitor, a tool included with Microsoft Systems Management Server (SMS). Network Monitor displays destination addresses in both ASCII and hexadecimal form.

Notes

The other kind of address in a packet or frame is the source address. This is the address of the host from which the packet originates (unless the source address is being spoofed).

device

Generally, any hardware component that can be driven by software. In Microsoft SQL Server, a file used to store databases.

Overview

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, you can manage devices and their drivers using Device Manager, which you access through the System utility in Control Panel. In Windows NT, you can view, enable, disable, stop, and start devices using the Devices utility in Control Panel. You can also install and uninstall devices and update device drivers in Device Manager.

In Microsoft SQL Server, a device is a file used to store SQL Server databases. Multiple SQL Server databases can be stored on a single device, and a single database can span multiple devices.

The master system device contains four databases:

- The master system database, which is used for tracking system-wide information
- The tempdb system database, which is used for temporary storage purposes
- The model system database, which is a template for generating new databases
- The msdb database, which is used by SQL Server Agent for scheduling alerts and jobs, and recording operators

Dfs

Stands for distributed file system, a network file system that makes many shares on different file servers look like a single hierarchy of shares on a single file server.

See: *Distributed file system (Dfs)*

DHCP

Stands for Dynamic Host Configuration Protocol, a protocol that enables the dynamic configuration Internet Protocol (IP) address information for hosts on an internetwork.

See: *Dynamic Host Configuration Protocol (DHCP)*

DHCP client

Software running on an Internet Protocol (IP) host that enables the host to have its IP address information dynamically assigned using Dynamic Host Configuration Protocol (DHCP).

Overview

The term *DHCP client* can also describe the software component on a computer that is capable of interacting with a DHCP server to lease an IP address.

Microsoft Windows comes with DHCP client software that you can configure when you install the TCP/IP protocol suite. This software allows a machine to immediately take its place in TCP/IP internetworks using DHCP. Other operating systems might require that the DHCP client software be installed and configured separately.

Microsoft operating systems that can function as DHCP clients include the following:

- Windows .NET Server
- Windows XP
- Windows 2000
- Windows NT
- Windows 98
- Windows 95
- Windows for Workgroups with the Microsoft TCP/IP-32 add-on installed
- Network Client 3 for MS-DOS
- LAN Manager 2.2c

Notes

On machines running Windows 2000, Windows XP, and Windows .NET Server, the DHCP client is DNS-aware and uses dynamic update for registering addresses, which allows the IP address and fully qualified domain name (FQDN) of client machines to be assigned and supported together.

Windows NT, Windows 95, and Windows 98 clients can release and renew their IP address leases using the `ipconfig` command. This command can also be useful

for resolving IP address conflicts or for troubleshooting DHCP clients and servers.

See Also: *DHCP server, Dynamic Host Configuration Protocol (DHCP)*

DHCP client reservation

A process for configuring a Dynamic Host Configuration Protocol (DHCP) server so that a particular host on the network always leases the same Internet Protocol (IP) address.

Overview

You can create a client reservation on a DHCP server if you want the server to always assign the same IP address to a specific machine on the network. You might do this to assign IP addresses to servers on the network because the IP addresses of servers should not change. (If they do, client machines might have difficulty connecting with them.) An alternative and more common way to assign a client reservation to a server is to manually assign a static IP address to the server.

On Microsoft Windows 2000– and Windows .NET Server–based networks you can create DHCP client reservations using the DHCP console, and in Windows NT you use DHCP Manager. Enter the media access control (MAC) address as the client's unique identifier. When the client with that address contacts the DHCP server to request an IP address, the server leases the reserved address to the client.

DHCP Client service

The service in Microsoft Windows 2000, Windows XP, Windows .NET Server, and Windows NT that implements the client component of the Dynamic Host Configuration Protocol (DHCP) on workstations and servers.

Overview

You can use the DHCP Client service to obtain Internet Protocol (IP) addresses and other Transmission Control Protocol/Internet Protocol (TCP/IP) configuration information from a DHCP server (such as a Windows 2000 or Windows NT server running the DHCP Server service).

Microsoft Windows includes support for DHCP and provides client software that lets you manage a machine's IP address over a network. This software runs as a service under Windows 2000, Windows XP, Windows .NET Server, and Windows NT. DHCP simplifies the administration and management of IP addresses for machines on a TCP/IP network.

DHCP console

A Microsoft Windows 2000 and Windows .NET Server administrative tool for managing the DHCP Server service on Windows 2000 Server and Windows .NET Server.

Overview

The DHCP console is the main tool used for managing and configuring all aspects of the Dynamic Host Configuration Protocol (DHCP) on a Windows 2000- and Windows .NET Server-based network and is implemented as a snap-in for the Microsoft Management Console (MMC).

DHCP console. The DHCP console for Windows 2000 Server.

You can use the DHCP console for the following standard DHCP administration tasks:

- Creating a scope of Internet Protocol (IP) addresses to lease to DHCP clients
- Creating a set of scope options, which are passed on to clients
- Configuring the lease duration for IP addresses leased to clients
- Viewing and terminating active leases on a network

- Creating reservations for servers that need specific IP addresses
- Monitoring DHCP statistics

The DHCP console also includes the following advanced features, which are new to Windows 2000 and are also included with Windows .NET Server:

- Automatic detection of rogue DHCP servers on the network
- Automatic self-assignment of temporary IP addresses to clients if a lease cannot be obtained from a DHCP server
- New DHCP options for multicast groups (class D IP addresses), superscopes for grouping together DHCP scopes for management purposes, and other vendor-specific functions
- Integration of DHCP and Domain Name System (DNS), allowing clients to use dynamic update to update their host names to IP address mappings in DNS server zone files

See Also: *Dynamic Host Configuration Protocol (DHCP)*

DHCP lease

The duration for which a Dynamic Host Configuration Protocol (DHCP) server lends an IP address to a DHCP client.

Overview

You can configure the lease duration using the Microsoft Windows NT administrative tool DHCP Manager or the Windows 2000 or Windows .NET Server console snap-in. If your Transmission Control Protocol/Internet Protocol (TCP/IP) network configuration does not change often or if you have more than enough IP addresses in your assigned IP address pool, you can increase the DHCP lease considerably beyond its default value of three days. However, if your network configuration changes frequently or if you have a limited pool of IP addresses that is almost used up, keep the reservation period short—perhaps one day. The reason is that if the pool of available IP addresses is used up,

machines that are added or moved might be unable to obtain an IP address from a DHCP server and thus will be unable to participate in network communication.

DHCP options

Additional Internet Protocol (IP) address settings that a Dynamic Host Configuration Protocol (DHCP) server passes to DHCP clients.

Overview

When a DHCP client requests an IP address from a DHCP server, the server sends the client at least an IP address and a subnet mask value. Additional information can be sent to clients if you configure various DHCP options. You can assign these options globally to all DHCP clients, to clients belonging to a particular scope, or to an individual host on the network.

You can configure a number of different DHCP options using the Microsoft Windows 2000 or Windows .NET Server snap-in DHCP console, but the options listed in the following table are the ones most commonly used by Microsoft DHCP clients. In Windows 2000- and Windows .NET Server-based networks, options 3, 6, and 15 are commonly used.

DHCP Options

Number	Option	What It Configures
003	Router	Default gateway IP address
006	DNS Servers	IP addresses of DNS servers
015	DNS Domain Name	Parent domain of associated DNS servers
044	NetBIOS over TCP/IP Name Server	IP addresses of Windows Internet Name Service (WINS) server
046	NetBIOS over TCP/IP Node Type	Method of NetBIOS name resolution to be used by the client
047	NetBIOS over TCP/IP Scope	Restricts NetBIOS clients to communication with clients that have the same scope ID

DHCP relay agent

A host that enables a Dynamic Host Configuration Protocol (DHCP) server to lease addresses to hosts on a different subnet than the one the server is on.

Overview

DHCP relay agents make it unnecessary to maintain a separate DHCP server on every subnet in an internet-work. Without DHCP agents, every subnet on an inter-network would need at least one DHCP server to provide address leases to hosts on that subnet. With DHCP agents, you can manage with only a single DHCP server for your entire internetwork (though two are recommended in case of failure).

DHCP relay agent. How a DHCP relay agent works.

Implementation

The DHCP relay agent is a machine with the DHCP Relay Agent service installed and configured to forward DHCP requests to a DHCP server on a different subnet (as shown in the illustration). The process happens as follows:

- 1 A DHCP client on the subnet where the DHCP relay agent is configured broadcasts a request for a lease from a DHCP server.

- 2 Since there is no DHCP server on the client's subnet, the DHCP relay agent picks up the client's request and forwards it directly to the DHCP server on another subnet.
- 3 The DHCP server responds to the request by offering a lease directly to the client.

Notes

You can configure Microsoft Windows NT, Windows 2000 and Windows .NET Server machines to operate as DHCP relay agents. To configure a machine running Windows NT Server as a DHCP relay agent, you must do the following steps:

- 1 Install the DHCP Relay Agent service using the Services tab of the Network utility in Control Panel.
- 2 Configure the DHCP server that the agent will pass requests to. Do this on the DHCP Relay tab of the Microsoft TCP/IP Properties sheet of the TCP/IP protocol.

To configure a Windows 2000 server as a DHCP relay agent, follow these steps:

- 1 Open the Routing and Remote Access console from the Administrative Tools program group.
- 2 Expand the server node to display General beneath IP Routing in the console tree.
- 3 Right-click General, and select New Routing Protocol from the context menu.
- 4 Specify DHCP Relay Agent in the New Routing Protocol dialog box, and click OK.
- 5 Open the property sheet for DHCP Relay Agent under IP Routing in the console tree, specify the IP address of the DHCP server to which lease requests should be relayed, and click OK.
- 6 Right-click DHCP Relay Agent in the console tree, and select New Interface to specify a router interface on which relay will be enabled.

DHCP scope

A range of Internet Protocol (IP) addresses that a Dynamic Host Configuration Protocol (DHCP) server can lease out to DHCP clients.

Overview

You configure the DHCP scope using the Microsoft Windows NT administrative tool DHCP Manager or the Windows 2000 and Windows .NET Server snap-in DHCP console. The IP addresses are leased for a specific Time to Live (TTL), usually three days. Information about scopes and leased IP addresses is stored in the DHCP database on the DHCP server. The values for IP address scopes created on DHCP servers must be taken from the available pool of IP addresses allocated to the network. Errors in configuring the DHCP scope are a common reason for problems in establishing communication on Transmission Control Protocol/Internet Protocol (TCP/IP) networks.

Notes

If non-DHCP clients have static IP addresses that fall within the range of the server's DHCP scope, these static IP addresses must be excluded from the scope. Otherwise, two hosts might end up with the same IP address, one assigned statically and the other assigned dynamically, resulting in neither host being able to communicate on the network.

See Also: *DHCP console*

DHCP server

A server that dynamically allocates Internet Protocol (IP) addresses to client machines using the Dynamic Host Configuration Protocol (DHCP).

Overview

DHCP servers perform the server-side operation of the DHCP protocol. The DHCP server is responsible for answering requests from DHCP clients and leasing IP addresses to these clients.

DHCP servers should have static IP addresses. A DHCP server gives DHCP clients at least two pieces of Transmission Control Protocol/Internet Protocol (TCP/IP) configuration information: the client's IP address and the subnet mask. Additional TCP/IP settings can be passed to the client as DHCP options.

Implementation

To have Microsoft Windows 2000 or Windows .NET Server function as a DHCP server, install the DHCP Server service and manage it using the DHCP console snap-in for the Microsoft Management Console (MMC). To have Windows NT Server function as a DHCP server, install the DHCP Server service and configure it using the administrative tool DHCP Manager. Note that a DHCP server should generally not be a DHCP client—that is, it should have a static IP address.

Notes

If hosts on a TCP/IP network are randomly losing connectivity with the network one by one, the DHCP server might be down and unable to renew leases for IP addresses obtained by the clients. Without a valid IP address leased to them, DHCP clients cannot communicate over the network.

DHCP Server service

The service in Microsoft Windows 2000, Windows .NET Server, and Windows NT that implements the server component of the Dynamic Host Configuration Protocol (DHCP) on Windows 2000, Windows .NET Server, or Windows NT Server.

Overview

The DHCP Server service is an optional networking component that can be installed on

- Windows NT Server by using the Network utility in Control Panel, selecting the Services tab, and adding the Microsoft DHCP Server service. When this service is installed on a machine running Windows NT Server, the administrative tool DHCP Manager is also installed.
- Windows 2000 Server and Windows .NET Server by using the Add/Remove Programs utility in Control Panel, selecting Add/Remove Windows Components, and selecting Dynamic Host Configuration Protocol (DHCP) from Networking Services. When this service is installed on a machine running

Windows 2000 Server or Windows .NET Server, the DHCP console administrative tool is implemented as a snap-in for the Microsoft Management Console (MMC).

Notes

The DHCP Server service should generally be installed only on a machine that has a manually assigned static IP address.

Dial-on-Demand Routing (DDR)

A method for connecting two remote networks together using Integrated Services Digital Network (ISDN) and dial-up Public Switched Telephone Network (PSTN) connections.

Overview

Dial-on-Demand Routing (DDR) is a procedure used in Cisco routers to connect two remote networks only when there is traffic to forward between them. DDR uses circuit-switched dial-up connections that must first be established for communications to take place and that are torn down when communications are finished. DDR is not the same as remote access: in remote access a computer connects with a remote network, but in DDR two networks are being connected together using routers.

DDR is a way of minimizing costs over wide area network (WAN) links. DDR is only active when data needs to be sent to the remote network, and this is generally cheaper than having a dedicated or leased line connecting the networks that is on all the time.

Implementation

DDR is typically implemented using ISDN for backup WAN connections when the primary WAN link is a

dedicated T1 line. DDR allows ISDN calls to be placed to one or more remote networks as required. These calls typically take less than 5 seconds to connect and begin transferring data. During the connection phase a switched circuit must be established between the networks. After the call is finished, this circuit is torn down after a prespecified idle time period has elapsed to save money. Since different circuits may be used for each DDR session, the quality of the connection can vary from session to session.

When used with ISDN, DDR allows different service types to be assigned to different kinds of traffic. Only traffic classified as “interesting” causes a dial-up session to be initiated—all other traffic is ignored by the DDR-capable router. A typical scenario might be to use DDR to connect when Simple Mail Transfer Protocol (SMTP) mail needs to be forwarded to a remote network. On a Cisco router you use the `dialer-list` command from the Internetwork Operating System (IOS) command set to specify which kinds of traffic are “interesting” from the standpoint of DDR. For IOS 11 and higher, DDR supports a number of different protocols including Internet Protocol (IP), Internetwork Packet Exchange (IPX), and Appletalk.

When implementing DDR for a WAN link, make sure you configure static routes to your remote network. Using dynamic routing will generate routing table advertisements that may trigger unwanted DDR sessions.

Notes

Dial-on Demand Routing (DDR) is different from Demand-Dial Routing (DDR), a Microsoft technology for forwarding packets on request across a Point-to-Point Protocol (PPP) WAN link.

dial-up line

Any telecommunications link that is serviced by a modem.

Overview

Dial-up lines are ordinary phone lines used for voice communication, but dedicated or leased lines are digital

lines with dedicated circuits. Dial-up lines are generally much less expensive to use, but they have less available bandwidth.

Companies often use dial-up lines for occasional, low-bandwidth usage (such as remote access networking) or as a backup for more costly dedicated lines. Dial-up lines are shared with all subscribers in the Public Switched Telephone Network (PSTN) domain, while dedicated or leased lines are allocated solely to the subscriber’s private telecommunications domain.

Besides dial-up lines using analog modems over local loop connections, there are also some digital services that can be dial up (instead of dedicated) in nature. These services include

- ISDN (Integrated Services Digital Network)
- X.25

See: *direct inward dialing (DID)*

differential backup

A backup type in which the only files and folders that are backed up are those that have changed since the last normal backup occurred.

Overview

Unlike an incremental backup, a differential backup does not clear the archive attribute for each file and folder. You can use differential backups in conjunction with normal backups to simplify and speed up the process. If a normal backup is done on a particular day of the week, differential backups can be performed on the remaining days of the week to back up the files that have changed since the first day of the schedule. Differential backups are faster than normal backups and use less tape or other storage media.

Notes

Differential backups are cumulative (unlike incremental backups), so when you need to do a restore, you need

only the normal backup and the most recent differential backup. Differential backups take longer to complete than incremental backups, but you can restore data from them faster.

Differentiated Services (DS)

A system for service classification of network traffic.

Overview

Differentiated Services (DS) was developed by the diff-serv working group of the Internet Engineering Task Force (IETF) as a framework for standardizing service classification mechanisms. DS manages network traffic based on the forwarding behaviors of packets instead of by traffic priority or application. DS is rule-based and can be used for policy-based traffic management.

Implementation

DS works by packaging Differentiated Services Code Point (DSCP) information within standard Internet Protocol (IP) headers. This DSCP information specifies the level of service required for the packet, and supports up to 64 different traffic forwarding behaviors. DSCP maps a particular packet to a packet hop behavior (PHB) applied by a policy to a DS-compliant router.

Diffie-Hellman (DH)

An encryption scheme used in public key cryptography.

Overview

Diffie-Hellman (DH) is an asymmetric encryption scheme that uses a key pair consisting of different public and private keys. The private key is used to encrypt the message, and the public key is used to decrypt it. DH also specifies a key exchange mechanism that allows private keys to be used over the Internet.

Another asymmetric encryption algorithm is RSA, developed by Ron Rivest, Adi Shamir, and Leonard Adleman. Asymmetric encryption schemes typically have much larger keys than symmetric schemes such as DES (Data Encryption Standard). A key for an asymmetric scheme is typically 10^{24} bits or larger. Asymmet-

ric encryption schemes form the basis of the Secure Sockets Layer (SSL) protocol used on the Internet.

Digital Advanced Mobile Phone Service (D-AMPS)

The digital version of the Advanced Mobile Phone Service (AMPS) cellular communications system.

Overview

AMPS is the oldest cellular phone system still widely deployed. It is an analog system operating in the 800 megahertz (MHz) band and is based on the EIA-533 standard.

Digital Advanced Mobile Phone Service (D-AMPS) is the digital version of AMPS and is based on the IS-54 standard. D-AMPS has been around since 1992, and it builds on the large installed base of AMPS cellular network installations. D-AMPS is used in North and South America and in parts of Asia and the Pacific region. The technical name for D-AMPS is Time Division Multiple Access/IS-136.

Implementation

D-AMPS uses the same 800 Mhz frequency band as AMPS, specifically frequencies between 824 and 891 MHz (although a dual-band 800/1900 MHz system has also been implemented). D-AMPS also uses 30-kilohertz (kHz) channels as AMPS does, but whereas AMPS can carry only one conversation per channel, D-AMPS can carry between three and six conversations. As a result, D-AMPS extends the capacity of AMPS from 50 conversations per cell to up to 300 conversations per cell, making D-AMPS more efficient in bandwidth utilization than AMPS.

While AMPS transmits information continuously, D-AMPS transmits in bursts over a time-shared system based on Time Division Multiple Access (TDMA) technology as the media access method. D-AMPS is more

immune to interference from noise than AMPS and can be scrambled to make it more secure (AMPS is very easy to eavesdrop on).

D-AMPS is cheaper and easier to implement than other digital cellular systems such as Code Division Multiple Access (CDMA), but its transmissions are not as secure as CDMA. D-AMPS represents a simpler upgrade path from AMPS than Global System for Mobile Communications (GSM), which also uses TDMA technology but does so in an incompatible format.

Digital Advanced Wireless System (DAWS)

A proposed standard for a multimegabit packet-switching radio network from the European Telecommunications Standards Institute (ETSI).

Overview

The Digital Advanced Wireless System (DAWS) will be compatible with the existing packet radio system called the Terrestrial Trunked Radio (Tetra), which enables terminals to communicate directly with each other in regions without cellular coverage.

DAWS is being developed in response to the rapid deployment of Global System for Mobile Communications (GSM) wireless cellular communication systems and the increasing demand for high-speed wireless mobile data services in response to the phenomenal growth of the Internet in recent years. The ultimate goal of the DAWS effort is to provide mobile wireless Asynchronous Transfer Mode (ATM) data communication services with full-terminal mobility over wide areas of roaming. ATM has been selected by ETSI as the technology of choice for the backbone of the future envisaged European Information Infrastructure (EII).

DAWS will be designed to support applications that require data rates in excess of the 2-megabit-per-second (Mbps) rate supported by the International Mobile Telecommunications-2000 (IMT-2000) standards, with eventual planned support for full ATM rates of 155

Mbps envisioned. Examples include wireless networking, Internet browsing, video conferencing, file transfer, and Voice over IP (VoIP).

Digital Audio Broadcasting (DAB)

A specification for broadband digital radio.

Overview

Digital Audio Broadcasting (DAB) is a specification for broadband transmission of digital information at speeds up to 2.4 megabits per second (Mbps). DAB is designed for transmission of digital audio and is envisioned as a replacement for existing analog AM/FM radio systems. DAB is a European specification only; however, a similar (but not interoperable) specification called IBOC (In Band, On Channel) is being developed in the United States.

Uses

Although DAB is intended mainly for audio broadcasting and is regulated as such, the possibility of it supporting digital data broadcasts, and even Internet access, are currently being explored. Since digital audio only requires 56 kilobits per second (Kbps), DAB's 2.4 Mbps bandwidth leaves lots of room for broadcasting location-based information such as weather reports, traffic information, airline arrivals and departures, stock quotes, and so on.

Britain leads the world in DAB deployment, with five channels already allocated to the BBC. Other European countries and regions are following with their own deployments. Psion has introduced a DAB receiver that plugs into the USB port of a PC to provide users with reception of DAB broadcasts, and other vendors are developing similar devices.

Although DAB is a broadcast (one-way) service, some carriers are envisioning using DAB to provide users with high-speed Internet access by using conventional or wireless modems for the upstream connection and DAB for downstream.

Prospects

DAB may gain the advantage over 2.5G and third-generation (3G) cellular systems such as General Packet Radio Services (GPRS) and Universal Mobile Telecommunications System (UMTS) by being first-to-market with high-speed location-based digital broadcast services. Spectrum licenses for DAB have cost only a small fraction of what carriers have bid for 3G licenses, allowing DAB providers more liquidity for rolling out deployments rapidly.

digital certificate

A technology similar to an identification card that can be used for verifying the identity of a user or service you are communicating with electronically.

Overview

Digital certificates are entities issued by certificate authorities (CAs), public or private organizations that manage a public key infrastructure (PKI). Digital certificates are the networking equivalent of driver's licenses, and they go hand in hand with encryption to ensure that communication is secure. Digital certificates verify the authenticity of the holder, and they can also indicate the holder's privileges and roles within secure communication. They can be used like driver's licenses for identification purposes or like bank cards (together with a password) to perform financial transactions in e-commerce and online banking. Digital certificates enable various rights, permissions, and limitations to be applied to their holders for various kinds of trusted communication purposes such as purchasing, government banking, benefits, and voting rights. The main function of a digital certificate is to associate a specific user with his public/private key pair.

Implementation

A digital certificate consists of data that definitively identifies an entity (an individual, a system, a company, or an organization). Digital certificates are issued by and digitally signed with the digital signature of the CA (once the CA has verified the identity of the applying entity). In addition to identification data, the digital

certificate contains a serial number, a copy of the certificate holder's public key, the identity and digital signature of the issuing CA, and an expiration date. The CA also maintains a copy of the user's public key in its centralized certificate storage facility.

Digital certificates are formatted according to an International Organization for Standardization (ISO) standard called X.509 v3. The X.509 standard specifies that a digital certificate must contain the following information fields:

- Version number
- Certificate serial number
- Signature algorithm ID used
- Name of certificate issuer
- Validity period (for certificate expiration)
- Subject name (name of certificate owner)
- Public key information for subject
- Unique identifier of certificate issuer
- Unique identifier of subject
- Extensions
- Digital signature for all the above fields

Uses

Digital certificates and public key cryptography are used in the popular Secure Sockets Layer (SSL) protocol, which provides secure transactions over the Internet. Several types of digital certificates are involved in this process, including

- CA certificate, which identifies the certificate authority, such as those based on Microsoft Certificate Server, and is used by Web browsers and Web servers to validate client and server certificates
- Server certificate, which identifies a Web server such as Microsoft Internet Information Services (IIS)
- Client certificate, which identifies a Web browser such as Microsoft Internet Explorer

Notes

A digital certificate is not the same as a digital signature. A digital certificate is a file that certifies the owner's identity, contains the owner's public key, and can be used to support encrypted communication. The purpose of a digital certificate is to certify that the user has the right to use the public/private key pair that has been issued by the CA. A digital signature, on the other hand, contains identity information along with the message or document itself (which has been hashed using the private key of the sender), and it confirms the identity of the sender and ensures that the content of the message has not been modified in transit.

In other words, to send an encrypted transmission, a user signs the message with a digital signature. But in order to be able to do this at all, the user must first be issued a key pair and its associated digital certificate.

digital dashboard

A technology based on Microsoft Office for customizing a user's interface to contain information from multiple data sources.

Overview

Digital dashboards allow users to consolidate business information from different sources such as personal folders, team folders, databases, messaging systems, Web sites, and so on. They provide a single, customizable user interface that helps users sift through and organize the mass of information crying for their attention in today's busy office environment.

Digital dashboards are designed to make knowledge workers more productive and help facilitate collaboration between teams of individuals. They are easy to build and customize and are based on standard Microsoft technologies, with Microsoft Outlook at the center of things.

Implementation

A digital dashboard in its simplest sense is a dynamic Web page displayed in Outlook. Outlook is the messaging and collaboration component of Office and acts as

the infrastructure on which digital dashboards are constructed. Using Office Web Components (OWCs), developers can build systems that can allow documents, messages, spreadsheets, databases, and charts to be generated and published from back-end systems and displayed through digital dashboards. Typical back-end systems that can support digital dashboards include Microsoft Exchange Server, which lets users create and share team folders for collaboration purposes, and Microsoft SQL Server, an online analytical processing (OLAP) repository for storing and analyzing business data.

You can download the Digital Dashboard Starter Kit from www.microsoft.com/business.

digital data service (DDS)

A family of leased line data communication technologies that provides a dedicated synchronous transmission connection at speeds of 56 kilobits per second (Kbps).

Overview

DDS was originally a trademark for an AT&T all-digital service running at 56 Kbps, but it has evolved into a general descriptor for a variety of digital services offered by different carriers under various names. Digital data service (DDS) is available in both a dial-up version called Switched 56 and a dedicated leased line service for continuous connections. The dial-up version can serve as a backup for the dedicated version. The more common dedicated version are lines with negligible connection establishment latency; they are always on and never busy.

Implementation

Typically, DDS uses four wires to support digital transmission speeds of 56 Kbps, but it is actually a 64-Kbps circuit that uses 8 Kbps for sending signaling information. Some vendors provide a variant of DDS with a data transmission rate of a full 64 Kbps—this service is sometimes called Clear 64.

DTo use DDS services for wide area network (WAN) connectivity, route packets from your local area network (LAN) through a bridge or a router, which is connected by means of a V.35 or RS-232 serial interface to a Channel Service Unit/Data Service Unit (CSU/DSU). The CSU/DSU is connected to the four-wire termination of the DDS line by means of an M-block connector, a screw terminal block, or some other connection mechanism. The Channel Service Unit (CSU) converts the data signal into a bipolar signal suitable for transmission over the telecommunications link. The DDS lines themselves use four wires and support speeds of 64 Kbps, but 8 Kbps of bandwidth is usually reserved for signaling, so the actual data throughput is usually only 56 Kbps.

Digital data service (DDS). Implementing DDS.

(DDS is only one example of a type of digital line; others include Integrated Services Digital Network (ISDN) and T1. DDS can be used in either multipoint or point-to-point communications and requires dedicated digital lines. DDS lines can also be used to connect buildings on a campus, usually with a maximum distance of about 3 miles (5 kilometers).

Notes

Another name for DDS is Dataphone Digital Service.

Digital Data Storage (DDS)

A tape backup technology that evolved from Digital Audio Tape (DAT) technologies.

Overview

Digital Data Storage (DDS) is a tape backup technology broadly used in all levels of businesses. DDS provides high capacity and performance at a relatively low cost. Although commonly called DAT instead of DDS, this is a misnomer and refers only to the type of tape employed.

Implementation

DDS records information on tapes using a helical scan method similar to that used in VCRs. Tracks are laid down at an angle in sweeps across the width of the tape, which allows DDS tape drives to operate at slower speeds than parallel-scan drives. The result of lower tape speeds is less wear and tear on both the tape and the drive.

DDS tape drives use a Small Computer System Interface (SCSI) interface to connect to backup servers. Most DDS tape drives are capable of simultaneous reading and writing of information.

DDS comes in different flavors that determine capacity and backup speed. For example, DDS-2 supports backup of 4 gigabytes (GB) of data at a transfer rate of 46 megabytes (MB) per minute, and DDS-3 lets you back up 12 GB at 70 MB per minute. Higher levels, such as DDS-4, exist for large enterprise networks. These storage figures are for uncompressed data (double them for compressed data).

DDS tapes are cheap (usually costing under \$10), which means that DDS is best used when your company's tape rotation scheme demands that a large number of tapes be used. DDS is a good solution for small to mid-sized companies implementing their first tape backup solution because it is inexpensive, easy to use, and performs well. The price of DDS tape drives starts at around \$1,000.

digital line

An umbrella term for various kinds of digital telecommunications services.

Overview

The distinguishing feature of a digital line is that it is digital from end to end and does not employ any kind of analog modem technologies. As a result, digital lines have higher traffic-carrying capacities, less noise, and better error-handling features than analog lines. The term *digital line* can refer to circuits based on the following:

- Digital data service (DDS)
- Integrated Services Digital Network (ISDN)
- T-carrier services such as T1 lines, fractional T1, and T3
- Switched 56 services

Digital Linear Tape (DLT)

A tape backup technology.

Overview

Digital Linear Tape (DLT) was developed in 1991 by Conner (later acquired by Quantum Corporation) as a tape backup solution for large companies. DLT tape drives can typically back up information at rates as high as 300 megabytes (MB) per minute. DLT tape drives typically cost \$10,000 or more and are available in robotic tape libraries as well as standard single-tape units. DLT was designed as an enterprise backup solution and is comparable to Exabyte Corporation's 8mm format in that respect.

Implementation

DLT is a channelized tape backup technology that allows multiple channels to be backed up simultaneously in parallel on a single tape. A DLT drive's tape head is stationary and has multiple read/write channels on it. As a result, DLT can back up information much more quickly than many other types of tape backup technologies such as 8mm or Digital Data Storage (DDS).

An example is Quantum's DLT 7000 series, which supports backup of 35 gigabytes (GB) uncompressed (70 GB compressed) at transfer speeds up to 5 MBps.

Notes

Quantum has recently developed an upgrade to DLT called SuperDLT, which competes with linear tape open (LTO) tape drive technology in speed and storage capacity.

digital modem

Any type of modem used for synchronous transmission of data over circuit-switched digital lines.

Overview

Unlike analog modems, which convert analog signals into digital ones using analog-to-digital converter (ADC) technologies, digital modems operate on end-to-end digital services.

A common example of a digital modem is an Integrated Services Digital Network (ISDN) terminal adapter, which uses advanced digital modulation techniques for changing data frames from a network into a format suitable for transmission over a digital line such as an ISDN line. Terminal adapters are thus basically data framing devices, rather than signal modulators such as analog modems, so in some sense the term *digital modem* is a misnomer because no modulation actually occurs.

digital nervous system

A paradigm created by Microsoft Corporation for electronic connectivity between businesses.

Overview

A digital nervous system enables businesses to create efficient, integrated systems that are easy to use and manage. The digital nervous system can be viewed as the next evolutionary phase of the Information Age.

The idea of this business paradigm is that businesses connect to each other in a way that is similar to the organization of a living organism. Digital information—

D whether it is text, graphics, audio, or video—flows between businesses much as electrical impulses flow between parts of the body. A stimulus of information entering one business that is generated by another business produces a response. The greater the complexity and the more interconnected the nervous system, the higher the organism—and the same applies to business. Greater interflow of digital information can lead to the evolution of new forms of doing business. The Internet and its related paradigms “intranet” and “extranet” serve as examples of this evolution. These concepts grew naturally—almost organically—from the complex interconnectedness fostered by advances in software and networking.

digital signature

An electronic signature that you can use to validate the identity of the sender of a digital transmission.

Overview

Digital signatures can be used to sign a document being transmitted by electronic means such as e-mail. Digital signatures validate the identity of the sender and ensure that the document they are attached to has not been altered by unauthorized parties during the transmission.

Uses

Digital signatures are mainly intended for signing documents that have a relatively short lifespan of no more than a few years. Examples include business contracts, invoices, and similar documents. They are not generally suited for documents requiring long-term archiving, such as medical or financial documents, because advances in cryptography might render them insecure

within the next decade or so. If you use digital signatures for documents that have to be archived for the long term, you need to also include a verification trail of how the documents are transmitted and stored. This evidentiary trail might be necessary should the authenticity of these signatures ever be challenged in court.

Implementation

Digital signatures are based on public key cryptography. In order for digital signatures to work, the sender must have both a digital certificate and a key pair issued by a certificate authority (CA) such as VeriSign.

A digital signature for a particular document is created by first performing a mathematical hash of the document. A hash is an iterative cryptographic process that employs a complex one-way mathematical function. To create digital signatures, a special hash called SHA-1 (Secure Hash Algorithm-1) is employed, and the end result of this process is a 160-bit text file called a message digest (MD). The MD is then encrypted using the sender's private key to create the digital signature, and the resulting signature is then attached to the document, which is then transmitted to its intended recipient. Note that each digital signature is unique and depends on the document being transmitted.

When the recipient receives the signed message, the same hash is performed on the received document to create a new message digest. The sender's public key is then applied to the MD, and the result is compared with the signature of the received message to determine whether the message is from its expressed recipient and whether it is intact or has been tampered with during transmission.

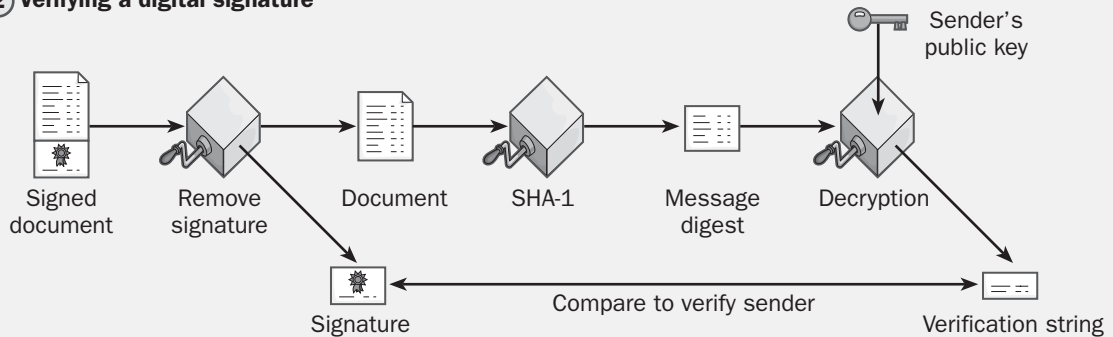

Marketplace

The complexity of public key cryptography and the wide variety of CAs in the marketplace have slowed the general adoption of digital signatures for sender verification purposes. In 2000, however, the U.S. government passed legislation called Esign (the Electronic Signatures in Global and National Commerce Act) that should speed widespread adoption of digital signatures. Esign basically makes digital signatures carry the same weight in law as regular signatures.

② Verifying a digital signature

Digital signature. How a digital signature is created and verified.

As a result of Esign, several vendors have started offering turnkey solutions for signing electronic documents that are designed to be as easy to use as sealing and stamping an envelope. Examples of such vendors include Digital Applications International, Silanis Technology, and signOnline. The first of these vendors to receive approval from a government agency was Silanis, whose Approvelit software was approved by the Food and Drug Administration (FDA) for government use.

A second group of vendors to emerge as a result of Esign consists of consulting companies whose products and services are designed to help large enterprises integrate digital signatures into their business processes. These vendors include Digital Signature Trust, NewRiver, Entrust Technologies, ValiCert, and DataCert.com.

A recent development that might lead to much wider use of digital signatures for signing documents is the implementation of public key infrastructure (PKI)

technology by the United States Postal Service (USPS). In 2001, the USPS announced NetPost.Certified, a service that uses an electronic postmark based on digital signatures and stored on smart cards to guarantee the identity and integrity of electronic transmissions. NetPost.Certified is currently available only when one of the parties involved (sender or receiver) is the U.S. government (where it should help streamline government by reducing the vast amount of paperwork needed for traditional document processing), but in a few years it is expected that the service will become more widely deployed in business use for signing contracts, deeds, affidavits, and other legal documents. The first U.S. government agency to use NetPost.Certified is the Social Security Administration, which uses it for vital statistics collections.

Issues

The weakest point in the digital signature process is making sure that the sender's private key is secure. The private key is normally stored on the hard disk of the sender's machine and is secured using a secret PIN

D (personal identification number) code known only to the sender. Because of its location on the hard drive, however, the private key is often vulnerable to hackers who break into networks to collect such information. Should hackers obtain a copy of your private key and somehow guess or determine your PIN code, they can sign electronic documents using your identity, and unless there is an evidential trail to the contrary, these signed documents would be legally enforceable.

To better protect the sender's private key, another new technology has emerged that may help propel the widespread use of digital signatures. This new technology is called Universal Serial Bus (USB) crypto-tokens, and it consists of a small device such as a smart card that securely stores the sender's private key in a medium inaccessible to hackers (you could, of course, still lose your USB token and land in trouble, but you could lose your driver's license as well, with similar results).

Digital Subscriber Line (DSL)

A group of broadband telecommunications technologies supported over copper local loop connections.

Overview

Digital Subscriber Line (DSL) was originally designed to provide high-speed data and video-on-demand services to subscribers. DSL is an always-on service such as Integrated Services Digital Network (ISDN) but works at much faster speeds compared to T1 (and even T3) leased lines for a fraction of the cost.

DSL uses the same underlying PHY layer as ISDN Basic Rate Interface (BRI) and is basically a form of modem technology that specifies a signaling process for high-speed, end-to-end digital transmission over the existing copper twisted-pair wiring of the local loop. DSL accomplishes this feat by using advanced signal processing and digital modulation techniques. DSL uses digital modems in which the digital signals are not converted to analog or vice versa; instead, the signals remain digital for the complete communication path from the customer premises to the telco's central office (CO).

DSL actually represents a family of related services commonly referred to as "xDSL," which includes the following:

- Asymmetric Digital Subscriber Line (ADSL):** This flavor of DSL is asymmetric in nature, with different upstream (customer to carrier) and downstream (carrier to customer) speeds. ADSL theoretically supports data rates of up to 6.1 megabits per second (Mbps) downstream and 640 kilobits per second (Kbps) upstream at distances of 18,500 feet (5340 meters) from the telco CO. In practice, however, typical ADSL speeds are more like 1 Mbps downstream and several hundred Kbps upstream. Because of its faster downstream speeds, ADSL is ideal for high-speed Internet access. ADSL is an American National Standards Institute (ANSI) standard called T1.413.
- G.Lite:** This is a variety of ADSL that was designed to be simpler to install at the customer's premises than regular ADSL (an external ADSL modem is used, and a splitter is not required at the customer's premises). G.Lite is an International Telecommunication Union (ITU) standard called G.992.2 and is sometimes called DSL Lite or ADSL Lite. Transmission rates for G.Lite range from 1.544 to 6 Mbps downstream and 128 to 384 Kbps upstream. G.Lite is growing in popularity as a "plug and play" form of DSL that customers can install themselves using DSL modems provided by providers. The disadvantage is that G.Lite generally has to be deployed using a second phone line because it provides unacceptable performance for voice transmission.
- Rate-adjusted Digital Subscriber Line (RADSL):** This is a form of ADSL that dynamically negotiates the best possible speed based on changing line conditions. Speeds for RADSL are comparable to those for ADSL.
- ISDN Digital Subscriber Line (IDSL):** This is essentially ISDN with no voice service, only data. IDSL provides 144 Kbps throughput in both directions, and unlike ISDN, it is always on and has no need for call setup.

- **High-bit-rate Digital Subscriber Line (HDSL):** This flavor supports high-speed, full-duplex communications over four-wire telephone lines at distances up to 12,000 feet (3650 meters) from a telco CO. HDSL provides equal upstream and downstream speeds of up to 1.544 Mbps, equal to a T1 line in throughput (it usually requires a conditioned line such as a T1 line as well). HDSL is usually deployed using bridges or routers instead of modems, and is best suited for wide area network (WAN) links.
- **Symmetric Digital Subscriber Line (SDSL):** This is a two-wire variety of HDSL that is the same in every respect except that it is half-duplex instead of full-duplex. Another name for this service is HDSL II.
- **Very-high-rate Digital Subscriber Line (VDSL):** This form of ADSL supports speeds of up to 54 Mbps upstream and 2.3 Mbps upstream over short distances of up to 1000 feet (305 meters). At longer distances the speed drops rapidly, and VDSL can rarely be provisioned beyond 4500 feet (1,370 meters) from the CO. VDSL is currently vendor-specific technology that has not been standardized, and because of its high speed and short distances, it is essentially a solution in search of a problem.

Uses

In the last few years, the use of DSL for residential broadband Internet access has skyrocketed, and DSL is currently the main competition for cable modem services to provide such services. DSL also can deliver other services to homes and businesses, including digital TV and Voice over DSL (VoDSL).

Another common use of DSL is for telecommuting (working remotely from home). DSL modems provide a cheap and easy way of gaining high-speed access to corporate intranets for telecommuters. DSL offers good security, performance, and reliability for telecommuters, but its distance limitation means that they must reside in metropolitan areas.

Many small to mid-sized businesses look on DSL as a replacement for aging 56 Kbps synchronous lines, ISDN lines, frame relay, and other traditional WAN services. DSL provides much higher bandwidth than these services, typically at half the cost or less. For example, although a T-1 line might cost more than \$1,000 a month, HDSL can provide similar throughput for less than \$400 a month.

Implementation

DSL can be deployed in different ways depending on the flavor being used. In ADSL, for example, an ADSL modem and a signal splitter are installed at the customer's premises and connected to the copper phone line. The splitter separates voice and data signals so that a single phone line can carry both voice and data. At the telco's CO, a Digital Subscriber Line Access Multiplexer (DSLAM) connects subscribers to a high-speed Asynchronous Transfer Mode (ATM) backbone, which typically uses a permanent virtual circuit (PVC) connection to an ISP for Internet access.

DSL modems can use a variety of signal coding methods, including carrierless amplitude and phase modulation (CAP) or discrete multitone (DMT) technology modulation, depending on the vendor's implementation, with CAP currently being the most popular modulation scheme used. DSL modems are simple Layer-2 devices that generally have few security features, lack remote management capability, and are intended for connecting a single computer to the Internet. For connecting an office LAN, a DSL router with built-in firewall and Network Address Translation (NAT) support is used instead of a DSL modem. All customer premises equipment (CPE) DSL devices are technically called ADSL Transmission Unit-Remote (ATU-R), and DSLAMs and similar DSL equipment at telco COs are known as ADSL Transmission Unit-Central office (ATU-C).

Advantages and Disadvantages

The main advantage DSL has over cable modem technology for delivering high-speed Internet access is that DSL uses ordinary phone lines to accomplish this, and such phone lines are everywhere. By contrast, cable TV,

D the service on which cable modem Internet access rides, has been widely deployed in residential areas but is rare in business districts and industrial parks. As a result, DSL has the advantage of having a ready-made wiring infrastructure, while cable companies have to invest money and effort to build their infrastructure out to business customers.

① Single-customer residential DSL

② Business DSL

Digital Subscriber Line (DSL). Implementing DSL for residential and business customers.

DSL is also inherently more secure than cable modem services and offers better throughput guarantees. This is because each DSL connection between subscriber and telco CO is a dedicated connection. By comparison, all cable modem users in a given neighborhood essentially operate as a shared local area network (LAN). As a result, cable modem users can often see each other's computers on the network, and the more cable modem users simultaneously accessing the Internet in a given neighborhood, the slower the download speed everyone will experience. By contrast, DSL line speeds are independent of other users and depend only on the distance from the CO and the backbone capacity of the carrier's connection to the Internet.

For businesses, DSL can provide wide area network (WAN) links that are faster and cost less than traditional WAN services such as Frame Relay and ISDN. Unlike ISDN and modem-based services, DSL is an always-on technology as well.

DSL does have several disadvantages, however, the most important being its distance limitations. DSL typically cannot be deployed beyond 18,500 feet (5340 meters) from a CO, and even within this distance, the farther the subscriber is from the CO, the worse the connection and slower the speed. DSL is thus restricted mainly to dense urban areas and is often not an option in rural areas. Using remote DSL access terminals, however, some regional bell operating companies (RBOCs) are pushing DSL farther out from the CO (see Issues below).

Another issue is that DSL may be impossible to deploy over older portions of the PSTN. This is because load coils and bridged taps often prevent DSL signals from passing between the customer's premises and the telco CO. Load coils are induction coils that shift frequencies upward for voice transmission to compensate for unwanted wire capacitance, and unfortunately this often shifts voice transmission into the frequency band used by DSL, causing interference. Bridged taps are a shortcut method for telcos to provide local loop phone services to customers without actually running dedicated

lines to those customers. Instead, an existing local loop line is tapped somewhere in the middle to run a line to a second customer. Too many such taps cause excessive echoes that can create noise that interferes with DSL signals. Finally, if a telco has fiber deployed anywhere along a local loop, DSL cannot be provisioned since it works only over copper and not over fiber (see Issues below).

DSL is also more difficult to provision than cable modem services. This is because to provision DSL typically requires the cooperation of three different companies: the DSL provider, which deploys the connection at the customer premises, the RBOC or inter-exchange carrier (IXC) from which the DSL provider purchases wholesale DSL services to retail to customers, and the ISP, which provides the actual connection to the Internet. As a result of this complexity, DSL provisioning can sometimes take weeks or even months, and when a connection goes down, finger-pointing among the different players can sometimes make for slow resolution of problems.

Finally, for business purposes traditional leased lines have a much better track record of reliability than DSL because of the aforementioned lack of cooperation among the DSL provider, RBOC, and ISP. T-1 lines are generally provisioned by a single company (the RBOC), which makes problems easier and quicker to troubleshoot. Medium and large companies often consider DSL an option for backup WAN services, but many are reluctant to make DSL their front-tier WAN service, despite the cost savings they can achieve by replacing their T-1 and fractional T-1 lines with DSL connections.

Marketplace

While most RBOCs offer DSL services, several independent DSL providers have recently appeared. However, some of these have failed or been acquired by RBOCs during the dot-com shakeout of 2000. Some of the larger players that remain in the pure-play DSL arena include Covad Communications Company, EarthLink, and Rhythms NetConnections. These providers are often classified as competitive local exchange carriers

(CLECs), though their services are generally limited to DSL. Other names sometimes used to describe them include competitive DSL providers and DSL local exchange carriers (DLECs).

DSL providers generally offer high-speed residential Internet access for service charges in the range of \$40 to \$60 a month. Business customers generally pay up to 10 times more, primarily because of additional services supported, such as providing access to multiple users on a LAN, managed firewalls, service level agreements (SLAs), and top-tier customer support.

Some DSL providers offer a service called bonding, which allows two or more DSL connections to be combined into a higher throughput connection. In a typical bonding scenario, two or four 144 Kbps DSL lines are connected to a DSL router and combined using MLPPP (Multilink PPP) into a single 576 Kbps connection. Bonding-enabled DSL routers are much cheaper to deploy at the customer premises than a DSLAM, which can accomplish the same thing but has greater space requirements.

Issues

A major issue that has hindered the widespread use of DSL is that different DSL vendors use proprietary solutions that make equipment from one vendor incompatible with that from another. This situation is particularly aggravating for businesses with offices scattered around geographically, as each office may use different equipment provided by different DSL providers or RBOCs. To overcome this issue, the OpenDSL initiative has been formed by 3Com Corporation, Cisco Systems, SBC Communications, Qwest Communications, and others. The goal of OpenDSL is to standardize all aspects of DSL the same way the Data Over Cable Service Interface Specification (DOCSIS) has done with cable modem technologies. Widespread acceptance of OpenDSL will likely drive DSL deployment further, especially in the business marketplace, but it is likely to take a few years for RBOCs and Competitive Local Exchange Carriers (CLECs) to replace their proprietary DSL systems with the new standard.

D

Although DSL appears to provide guaranteed throughput due to its dedicated connection (as opposed to shared-LAN cable modem services, where throughput decreases for each user as more users come online), such guarantees may not take into account the back-end configuration at the telco CO. For example, the DSLAM at the CO may become a bottleneck when multiple DSL subscribers all try to simultaneously download large files from the Internet. Even if the DSLAMs can scale to meet demand, the DSL provider's connection to the ISP can also be a bottleneck, particularly if the DSLAM is not colocated at the ISP's point of presence (POP). Business customers should be certain that the DSL provider they are considering working with has adequate DSL equipment at the CO end of the connection to guarantee the level of service they desire.

In an attempt to overcome DSL's distance limitation of 5.6 kilometers (3 miles) from the telco CO, some RBOCs have begun deploying remote DSL access terminals that are located within that distance of potential subscribers while being connected to the CO using fiber. This configuration allows RBOCs to push DSL out to remote neighborhoods to gain additional customers but has provoked a reaction from some pure-play DSL providers as it makes their own deployments difficult or impossible. This is because the fiber between the remote terminal and the CO makes it impossible for the DSL provider to provision DSL to customers directly from the CO (DSL cannot be provisioned over fiber). Furthermore, these remote terminals are often installed inside digital loop carrier (DLC) systems, small boxes deployed by RBOCs in neighborhoods, and these DLCs may not have sufficient space within them for DSL providers to deploy their own equipment to provision their own pushed-out DSL services (even if there is sufficient space, this means another costly expense for cash-strapped DSL providers). An example of this is Project Pronto, being deployed by SBC Communications, an RBOC. DSL remote terminals are sold by Alcatel, Lucent Technologies, and other vendors.

Prospects

Prospects are uncertain for some pure-play DSL providers. This is because the success of their DSL deployments depends on cooperation with both the RBOCs from which they lease local loop access and the ISPs they partner with to provide their DSL customers with Internet access. Nevertheless, DSL providers remain a popular choice for business customers seeking DSL services, mainly because such providers generally offer better service than some traditional RBOCs that have not yet adjusted to the new economy way of doing business. Pure-play DSL providers can also provide nationwide coverage compared to the regional coverage of most RBOCs, and this appeals to companies that have branch offices scattered geographically, but such rollouts are complicated by the fact that the DSL provider has to work with multiple RBOCs and ISPs to make everything work properly for such customers.

RBOCs, however, often have the advantage of having deeper pockets, which may give them a competitive edge in the long run over many competitive DSL providers. Furthermore, some larger RBOCs such as SBC Communications and Qwest are planning nationwide rollouts of DSL through partnerships and mergers with other providers.

An emerging technology that may help competitive DSL providers grow market share is line sharing. This technology lets a CLEC provision DSL to a customer over the same local loop connection that the RBOC uses to provide the customer with voice telephone service. In this way the DSL provider does not have to roll out a second phone line to the customer, which often takes weeks because it must be done in cooperation with the RBOC.

Notes

If you are using a DSL connection to the Internet, check with your DSL provider before you try to use it to deploy a public Web server, or else you might find your DSL service unexpectedly cut off once they discover what you are doing.

Digital Subscriber Line Access Multiplexer (DSLAM)

The DSL termination device at a telco central office (CO).

Overview

The Digital Subscriber Line Access Multiplexer (DSLAM) is an Asynchronous Transfer Mode (ATM) access device installed at the CO of a DSL provider. DSL lines coming from multiple subscribers terminate at the DSLAM and are multiplexed together to ride on the provider's ATM backbone, typically through a permanent virtual circuit (PVC) to an Internet service provider (ISP) to provide customers with Internet access.

A typical DSLAM can aggregate up to 100 DSL customer connections. Multiple DSLAMs are required for larger numbers of subscribers. DSLAMs usually have minimal support for quality of service (QoS) as they are often required to split off voice traffic from Internet Protocol (IP) data, and voice traffic is delay-sensitive in nature. Since DSLAMs usually package IP traffic into ATM cells, they cannot distinguish between different kinds of IP traffic to provide different levels of service to these different types of traffic. For service to customers who need to transport both voice and data traffic, telcos must set up a different PVC for each type of traffic and for each customer, which means that managing and configuring DSLAMs is a lot of work for a DSL provider that is rolling out thousands of DSL lines to customers. For example, if 50 customers need both voice and data DSL services, then 100 PVCs will need to be configured.

DSLAMs usually support only one kind of DSL service, but now reaching the market are newer DSLAMs are that support multiple services (including

Asymmetric Digital Subscriber Line [ADSL], ISDN Digital Subscriber Line [IDSL], and Very-high-rate Digital Subscriber Line [VDSL]) across thousands of ports in a single device. These new DSLAMs have greater QoS support to enable them to carry Voice over DSL (VoDSL) services in addition to traditional wide area network (WAN) and Internet access services. Some new DSLAMs also act as concentrators, allowing traffic to be aggregated according to type. Thus if 50 customers require both voice and data DSL services, only two PVCs need to be configured, one for voice traffic and the other for data.

Marketplace

Some of the vendors offering state-of-the-art DSLAM equipment include Nortel Networks, Lucent Technologies, Paradyne, and Copper Mountain.

digital transmission

Transmission of signals that vary discretely with time.

Overview

Digital transmission signals vary between two discrete values of some physical quantity, one value representing the binary number 0 and the other representing 1. With copper cabling, the variable quantity is typically the voltage or the electrical potential. With fiber-optic cabling or wireless communication, variation in intensity or some other physical quantity is used. Digital signals use discrete values for the transmission of binary information over a communication medium such as a network cable or a telecommunications link. On a serial transmission line, a digital signal is transmitted 1 bit at a time.

Digital transmission.

The opposite of digital transmission is analog transmission, in which information is transmitted as a continuously varying quantity. An analog signal might be converted to a digital signal using an analog-to-digital converter (ADC) and vice versa using a digital-to-analog converter (DAC). ADCs use a method called “quantization” to convert a varying AC voltage to a stepped digital one.

direct burial fiber-optic cabling

Fiber-optic cable designed for burial.

Overview

Direct burial fiber-optic cable typically consists of multiple fiber-optic cables bundled together and enclosed in a protective sheath. Direct burial fiber-optic cabling is designed to be buried in trenches and contains a gel filling that protects the individual fibers from temperature and moisture variations. A strip of strengthening material runs axially down the cable to prevent excessive bending, which can fracture the individual fibers. Direct burial cabling can have steel-armor construction with heavy waterproof polyethylene jackets and can contain either multimode or single-mode fiber-optic strands.

Direct burial fiber-optic cabling. Deploying direct burial fiber-optic cable to connect networks in different buildings.

Uses

Direct burial cabling is more cost-effective than single-fiber cabling for long outdoor cable runs between buildings or across a campus because it allows for future bandwidth upgrades.

Direct Cable Connection

A Microsoft Windows tool that facilitates file transfers between two non-networked computers.

Overview

Direct Cable Connection can be used on Windows 95, Windows 98, Windows 2000, Windows XP, and Windows .NET Server to establish a temporary network connection for the purpose of transferring files between machines. Direct Cable Connection is implemented using a serial null-modem cable or a standard parallel cable. One computer must be designated as the host (the server) and the other as the guest (the client). The desired resources must be shared on the host computer, and Dial-Up Networking must be installed on the guest computer.

If desired, the host computer can also act as a router that allows the guest computer to access resources on other computers on the host computer's network.

directed frame

A frame that is being sent by one station to a specific destination station on the network.

Overview

On an Ethernet network, a directed frame is one that uses the hexadecimal MAC address of a specific target machine on the network as its destination address. The directed frame is picked up by the target machine and is ignored by all other machines on the network.

Directed frames are used for most network communication because they are the most efficient type of frame for communication. However, some services, such as network announcements, require that all stations on the network receive a frame. To send a frame to all stations

on the network, you use a broadcast frame instead of a directed frame.

directed packet

An Internet Protocol (IP) packet that is being sent by one host on a Transmission Control Protocol/Internet Protocol (TCP/IP) network to a specific destination host on the network.

Overview

A directed packet contains the IP address of a specific target host on the network as its destination address. The directed packet is picked up by the target host and is ignored by all other hosts on the network.

Directed packets are used for most network communication on a TCP/IP network because they are the most efficient method for communication. However, some services, such as network announcements, require that all hosts on the network receive a packet. To send a packet to all stations on the network, you use a broadcast packet instead of a directed packet.

Direct Internet Message Encapsulation (DIME)

A protocol for encapsulating attachments to Simple Object Access Protocol (SOAP) routing protocol messages.

Overview

Direct Internet Message Encapsulation (DIME) is a protocol for encapsulating multiple payloads of arbitrary type and size for transmission in a single message construct. DIME is lightweight in nature and encapsulates binary information for transmission within SOAP messages. Since SOAP is based on Extensible Markup Language (XML), DIME performs a similar function to what Multipurpose Internet Mail Extensions (MIME) does for Simple Mail Transfer Protocol (SMTP) messages: provide a method for encoding binary

attachments into text. The difference between DIME and MIME is that DIME is much simpler and faster to parse than MIME.

D

DIME can be used to encapsulate any binary information, including image files, XML data, and so on. DIME allows multiple logically connected records to be aggregated into a single message. DIME does not specify the type of messages being sent and can be used over any connection-oriented or virtual logical circuit.

Implementation

The DIME encapsulation format specifies only three additional pieces of information for each payload: the length of the payload in bytes, the type of payload (to allow routing of messages according to application type), and a payload identifier, which is basically a globally unique identifier (GUID).

direct inward dialing (DID)

A service provided by a local exchange carrier (LEC) to a corporate client.

Overview

Direct inward dialing (DID) uses a Private Branch Exchange (PBX) that allows outside callers to dial individuals within the company directly. Typically, the LEC allocates a block of phone numbers to the company, usually differing only in the last two, three, or four digits. For example, a company with 50 employees who each need a separate phone number could be assigned the numbers 555-1201 through 555-1250. Outside callers could dial the employees directly using these numbers, which are routed through perhaps only eight trunk lines that service the PBX, supporting a maximum of eight simultaneous calls. Inbound calls are routed by the PBX to the appropriate extension.

directory

A tool designed to provide a single source for locating, organizing, and managing network resources within an enterprise.

Overview

Directories are used in enterprise networks to organize network resources so that they can easily be found and managed. These network resources typically include computers, disk volumes, folders, files, printers, users, groups, and other types of objects. Directories are typically used for one of two general purposes:

- **Internal directory:** These are directories used within the corporate network for publishing information about users and resources within the enterprise. A company's internal directory may be accessible to employees when they are outside the company network using a secure connection such as a virtual private network (VPN) connection, but it is not accessible to non-employees.
- **External directory:** These are directories typically located on servers in the perimeter network or demilitarized zone (DMZ) at the boundary between the corporate local area network (LAN) and the public Internet. External directories are typically made available to customers, clients, and business partners to provide them with selected business information such as catalogs and so on.

Network operating systems (NOSs) typically have their own directories built into them. This NOS directory functions much like the yellow pages of a phone book. For example, if you look up the word *printers*, you will find a list of available printers and information for accessing them. Examples of NOS directories include Windows NT Directory Services (NTDS) for Windows NT, Active Directory for Windows 2000, and Novell Directory Services (NDS) for Novell NetWare version 4 and higher.

Many applications use their own proprietary directories. An example is Microsoft Exchange 5.5, which uses a proprietary Exchange directory service based on the Microsoft Jet database. The more recent Exchange 2000 instead uses the Active Directory directory service of Windows 2000 for storing its hierarchy of information concerning Exchange directory objects.

An international standard has long existed for how directory services should operate and directory databases be structured. This standard, called X.500, was developed by the International Organization for

Standardization/International Electrotechnical Commission (ISO/IEC) in the 1980s. The X.500 standard specifies a protocol called Directory Access Protocol (DAP) that enables users and applications to search and modify an X.500 directory. Because DAP is complex and difficult to implement, a simpler protocol called Lightweight Directory Access Protocol (LDAP) was developed later on and has become the de facto standard for directory protocols. Active Directory, the directory service used by Windows 2000 and Windows .NET Server, is LDAP-compliant.

To function at the enterprise level, a directory should have the following essential characteristics:

- It should be scalable, so that it can grow to accommodate information and provide services as the enterprise itself grows.
- It should be extensible and have a schema that can be modified by adding new classes, objects, and attributes.
- It should provide simple ways of finding directory objects
- It should be possible to administer it from a single point on the network.

Active Directory for Windows 2000 and Windows .NET Server satisfies all these conditions.

Implementation

A directory typically consists of the following two components:

- **Directory database:** A hierarchical database structure that contains the actual information about the resources on the network.
- **Directory service:** Software that allows you to search for and locate information stored in the directory database.

In addition to these two components, consideration must be given to where the directory database is stored. This database is typically located on directory servers that are located at different points on the network. The database can be stored in the following ways on these servers:

- **Distributed:** In this scenario each directory server contains only a portion of the directory database for which it is authoritative. An example of a distributed directory service is the Domain Name System (DNS) found on the Internet.
- **Single-master:** Here one directory server contains a writeable master copy of the database, while all other directory servers contain read-only copies of this database. When changes need to be made to the directory, they are made first to the master server and then later copied to the other servers on the network. An example where this is used is in a Windows NT domain.
- **Multimaster:** Here each directory contains a writeable copy of the entire directory database. Modifications may be made to any directory server on the network, and these modifications are then automatically propagated by means of directory replication to all other servers on the network. An example of a multimaster directory is Windows 2000's Active Directory.

Marketplace

While Active Directory and NDS are the most popular general NOS directory products, there are also third-party directories that the enterprise architect may consider. One of the most popular of these is iPlanet's Directory Server, an LDAP server that is highly optimized for rapidly performing LDAP queries. Another is Novell's eDirectory, which is NDS uncoupled from the Novell NetWare NOS and made available for other platforms. Still another LDAP-compliant directory on the market is InJoin from Critical Path. Other popular directory vendors include Oracle Corporation and Innosoft International.

Some factors to consider when evaluating directory software for purchase for the enterprise environment include

- **Security:** Access to the directory can be managed by access lists and by policies. Some vendors provide additional tools for managing directory security. Examples of such vendors include Netegrity and Oblix.

D

- **Access method:** Nowadays everything needs to be Web-enabled, and information within an enterprise directory should be accessible by issuing LDAP queries over Hypertext Transfer Protocol (HTTP) through a simple Web browser.
- **Management tools:** Directories that can be managed using LDAP/HTTP are a distinct advantage over others where remote administration is concerned.
- **Namespace design:** Most general-purpose NOS directories map a company's geographical structure to its directory namespace. This may be the simplest and most logical thing to do, but whether it is most efficient for LDAP searching is something that you should consider before implementing the directory. For a company that has already implemented its directory but has trouble searching it efficiently, a product called RadiantOne from Radiant Logic can help by mapping a virtual LDAP namespace over the top of the existing namespace to speed search queries and maintain directory independence when the network configuration is changed.

Issues

The main issue confronting the enterprise concerning directories is interoperability. A large enterprise typically has many different directories implemented at various levels of its network, and consolidating all these directories into a single directory through migration is often impractical from the point of view of cost (large enterprises tend to be heterogeneous in many ways and for many reasons).

To allow directories from different vendors to share information with one another, a number of metadirectory products has appeared in the marketplace. Examples of metadirectory software include Microsoft Metadirectory Services (MMS) and Novell's DirXML.

Another issue regarding interoperability between directories is that the LDAP standard has certain limitations that require directory vendors to add their own proprietary extensions to LDAP if they want to give their LDAP directory products greater functionality. Thus even different LDAP-compliant directories from different vendors might not be able to interoperate to a desired degree. To solve this problem, an XML lan-

guage called Directory Service Markup Language (DSML) is being developed to better allow different directories to communicate with one another. Other related initiatives include Simple Object Access Protocol (SOAP) and the Universal Description, Discovery, and Integration (UDDI) specification.

Finally, it must be mentioned that simply implementing a directory will not necessarily save costs for an enterprise or make the lives of administrators easier. Directories can be complex to implement, especially if legacy information needs to be migrated to them. Also, tools for managing directories can be difficult to use and require extensive training. As a result of such complexity, industry analysts estimated that as of 2000 less than 35 percent of all companies were using LDAP directories.

Directory Access Protocol (DAP)

A protocol for accessing information in a directory service based on the X.500 recommendations.

Overview

The Directory Access Protocol (DAP) specifies how an X.500 Directory User Agent (DUA) communicates with a Directory System Agent (DSA) to issue a query. Using DAP, users can view, modify, delete, and search for information stored in the X.500 directory if they have suitable access permissions.

DAP is a complex protocol with a lot of overhead, which makes it generally unsuitable for implementations in a Microsoft Windows environment. A simpler version called Lightweight Directory Access Protocol (LDAP) is growing in popularity and can be used to access and update directory information in X.500 directories. LDAP is more suitable than DAP for

implementation on the Internet and has mostly superseded DAP as an access protocol for X.500-based directories (which are now often called LDAP directories).

directory database

The central store of directory information on a network.

Overview

The directory database is one of two components of a typical directory application, the other being the directory service, which allows the directory database to be searched and modified.

In Microsoft Windows NT, Windows 2000, and Windows .NET Server, the directory database resides on the domain controllers, which manage all security-related aspects of the network. In Windows NT, the directory database is generally called the Security Accounts Manager (SAM) database. In Windows 2000 and Windows .NET Server, the directory database is the database component of Active Directory directory service.

Both the SAM database and the Active Directory directory service store information about objects on the network. The SAM is limited to storing information about users, groups, and computers that participate in the domain and security policy information such as password expiration policies and audit policies. The SAM stores its information in a privileged area of the registry. The practical upper limit for a SAM database is 40 megabytes (MB), which corresponds to approximately 26,000 user and computer accounts. If an enterprise has more than 26,000 users, the Windows NT directory database can be partitioned (split) into two or more portions and trust relationships can be configured according to a multiple master domain model.

Active Directory is considerably more flexible and powerful than the Windows NT SAM. Active Directory scales upward to tens of millions of objects, and these objects may be users, groups, computers, printers, shares, and many other forms of information.

Directory Enabled Network (DEN)

An initiative toward a platform-independent specification for storing information about network applications, devices, and users in a directory.

Overview

Directory Enabled Network (DEN) was started by Microsoft Corporation and Cisco Systems in 1997 with the goal of developing standards for directory-based management of network resources. DEN is a policy-based mechanism that binds a user's name and network access profile to a policy. This procedure maps users to network services to make a more intelligent network that can better manage its resources, especially bandwidth. User rights on the network and bandwidth allocation can then be assigned to the user by using the profile.

DEN's goal is to unify the disparate network management platforms in existence today to provide a single, directory-based, cross-platform specification for the development of standard network management systems. The DEN initiative is now managed by the Distributed Management Task Force (DMTF) and is open to network device vendors, Internet service providers (ISPs), independent software vendors (ISVs), carriers, and others who might be interested.

Prospects

DEN has not materialized as fast as many had hoped, but the Desktop Management Task Force (DMTF) is still guiding it toward final release within the next few years. Part of this is because one of the major driving forces initially behind DEN was the hope of managing quality of service (QoS) policies using directories. This would allow bandwidth to be allocated to users and applications more easily. The pressure to do this has lessened in the last few years, however, as bandwidth costs continue to drop, especially with the emergence of Gigabit Ethernet (GbE). As a result, QoS issues can be sidestepped in many situations simply by overprovisioning bandwidth. Furthermore, simple Internet Protocol (IP) QoS techniques such as 802.1p have lessened the need for more complex directory-based QoS schemes.

Technical issues have also hindered the development of DEN as a real-life specification. One recent step forward involved the mapping of Common Information Model (CIM) schema to Lightweight Directory Access Protocol (LDAP) so that CIM object information could be stored and accessed in LDAP-compliant directories such as Microsoft's Active Directory directory service.

directory export

The process of exporting information from a directory to another application.

Overview

An example of directory export can be found in Microsoft Exchange Server, which supports the exporting of information about recipients stored in its directory database. This information can be exported to a comma-delimited text file (.csv file), edited, and then imported into another system.

Directory export. Configuring directory export for Exchange Server.

For example, you can import recipient information into a spreadsheet to print it out. Or you can export the information into a spreadsheet, use spreadsheet functions to mass-modify certain fields, and then use directory import

for re-importing the modified account information back into Exchange. Using directory export/import is in fact the usual method in Exchange for modifying the properties of a large number of recipients at one time.

directory hierarchy

The hierarchy of objects in a directory.

Overview

Directories typically store information about the objects they manage in a hierarchical fashion. As an example we can consider the containers and leaf objects in a Microsoft Exchange Server directory, which is displayed and configured using the Exchange Administrator program. This hierarchy is based on the directory recommendations given by X.500.

Directory hierarchy.

The Exchange directory hierarchy begins at a root object called the Organization container, and then branches down into sites, servers, connectors, recipients, and other objects. To configure any object in the directory hierarchy, you use its property sheet.

Objects in the directory hierarchy of Exchange come in two types:

- **Containers:** These can contain other directory objects. Containers usually also have configurable properties.

- **Leaf objects:** These are end nodes in the directory tree and whose properties can be configured using their property sheets.

See Also: *directory, Exchange Server, X.500*

directory import

The process of importing information into a directory from another application.

Overview

An example of directory import can be seen in Microsoft Exchange. Here the information to be imported must be in a format that the importing system can understand, usually a delimited text file such as a .csv file. Microsoft Exchange Server allows recipient information to be imported into its directory database and allows recipients exported from other mail systems to be imported into Exchange. For example, you can use the Exchange Migration Wizard to extract mailbox information from a foreign mail system into a .csv file. You can then import this information into a spreadsheet program such as Microsoft Excel, modify it as needed, and import it into Exchange to create new mailboxes in your organization for users of the foreign mail system who are migrating to Exchange.

directory replication (Windows 2000 and Windows .NET Server)

A process that ensures that all directory servers contain identical copies of the directory database.

Overview

In a typical implementation of a directory, the directory database is replicated to a number of servers called directory servers. These servers are located at different points around the network to provide accessible points for clients needing to search the directory for resources on the network.

Implementation

As an example of the directory replication process, consider the Active Directory directory service in

Microsoft Windows 2000 or Windows .NET Server, which stores copies of the directory database on machines called domain controllers. In Windows 2000, directory replication is thus the process of replicating Active Directory updates to all the domain controllers on the network. Directory replication ensures that users have access to resources on the network by ensuring that information about users, groups, computers, file shares, printers, and other directory objects is current on all domain controllers in the network.

Directory replication of Active Directory on a Microsoft Windows 2000– or Windows .NET Server–based network takes place in two ways, depending on whether the participating domain controllers are in the same site.

- **Intrasite:** Within a site, intrasite replication between domain controllers uses remote procedure calls (RPCs) by means of a dynamically allocated port number. This replication takes place automatically every five minutes. Domain controllers within a site exchange update information in a ring fashion, from one domain controller to another. This ring topology is established by a process called the Knowledge Consistency Checker (KCC) and ensures a minimum of two replication paths between each pair of domain controllers and a maximum replication hop count of three to support efficient replication and fault tolerance.
- **Intersite:** Between sites, intersite replication can use RPCs if the local area network (LAN) or wide area network (WAN) connection supports them or some other method, such as Simple Mail Transfer Protocol (SMTP) e-mail messages. Intersite replication uses a compressed format for more efficient use of slow WAN links and is easier to schedule and manage than intrasite replication. To take advantage of the greater flexibility of intersite replication and to use it instead of intrasite replication, configure your domain controllers to belong to more than one physical site.

directory replication (Windows NT)

In Microsoft Windows NT, the replication of a tree of folders from one server to another using the Directory Replicator Service.

Overview

The Directory Replicator service is a Windows NT service for replicating files and folders over the network. The Directory Replicator Service simplifies the task of updating key network configuration files needed by all users, such as system policies and logon scripts. You can also use directory replication to load balance between multiple servers when a large number of users need access to specific files or folders.

You can perform directory replication in Windows NT to create and manage identical directory structures on different Windows NT servers and workstations. When a change is made to the master directory structure, such as modification of a file or addition of a directory, that change is replicated to the other computers. One use for directory replication is to provide a means for load balancing file system information across several servers. This allows more clients to efficiently access the data stored in the replicated directory structure because identical data is stored on different machines. For example, you might replicate a database of customer information across several servers in your network to provide easier access. You can also use directory replication to copy logon scripts from a primary domain controller (PDC) to a set of backup domain controllers (BDCs). You can configure replication to occur between different computers in a domain or from one domain to another.

Implementation

The Directory Replicator Service replicates files from an export computer to an import computer. The export computer must be running the Windows NT Server operating system, but the import computer can run Windows NT Server, Windows NT Workstation, or LAN Manager for OS/2 servers.

The export server is the computer that contains the master copy of the directory tree to be replicated. This

export server must be a machine running Windows NT Server. The computers that will replicate with the export server are called import servers. Import servers can be machines running Windows NT Server, Windows NT Workstation, or LAN Manager Server.

Prior to configuring directory replication, you must create a new user account as a security context within which the replicator service will run. This account should have a password that never expires and should be a member of the Replicator, Domain Users, and Backup Operators groups. The account should be accessible from both export and import machines. Use the Services utility in Control Panel to configure the Directory Replicator Service to start automatically upon system startup and to use your new account for logging on.

Server Manager is the administrative tool used for configuring replication in Windows NT. You can configure replication to occur either immediately after a change is made to the directory structure or after a stabilization period. When configuring replication, you select one of the following options:

- Replicate the entire subtree of directories and files beneath a specific directory on the export server.
- Replicate only specific files contained in the subtree by applying locks to its directories and files to prevent them from being exported.

By default, the export directory in which the master copy of the replicated data is contained is located in the path %SystemRoot%\system32\repl\export. The default path to which the directory structure is imported on the import server is %SystemRoot%\system32\repl\import.

Notes

Do not use directory replication as a substitute for a regular program of tape backups. The Directory Replicator Service can create a lot of network traffic and should not be used for backing up data across a network. If the data you are replicating contains large files that change frequently, replication traffic can cause network congestion unless you watch it carefully. Be especially careful when you replicate directory structures over

slower wide area network (WAN) links to avoid congestion that interferes with other essential forms of traffic such as logon traffic.

The Directory Replicator Service on Windows NT can export only one directory tree from a given export server. It is a good idea to leave the default export location as it is and move the directory structure and information you want to replicate to this default export location. This allows you to also replicate logon scripts because by default these are located on a PDC in the location %SystemRoot%\system32\repl\export\scripts and on a BDC in the location %SystemRoot%\system32\repl\import.

Since these script directories are located within the default export and import paths, they can be replicated along with other data.

directory service log

A log that contains events written by the Active Directory directory service on machines running Microsoft Windows 2000 or Windows .NET Server.

Overview

The directory service log exists only on domain controllers because these are the only computers that have copies of Active Directory. The directory service log contains events such as informational, warning, and error events concerning operations that have been performed on or by Active Directory. These events reveal the state of Active Directory and can be used for diagnostic and troubleshooting purposes.

Information in the directory service log can be displayed using Event Viewer, a Windows 2000 and Windows .NET Server administrative tool that runs as a snap-in for the Microsoft Management Console (MMC). Event Viewer for Windows 2000 and Windows .NET Server supports a number of different kinds of logs in addition to the three supported in the Windows NT version of Event Viewer, namely, the system log, security log, and application log. The actual types of event logs available in Windows 2000 and Windows .NET Server Event Viewer depend on which optional networking components are installed on the machine.

Directory Service Manager for NetWare (DSMN)

An optional Windows 2000 utility for managing directory information stored on NetWare servers.

Overview

Directory Service Manager for NetWare (DSMN) enables Windows 2000 domain controllers to manage account information on NetWare 2.x, 3.x, and 4.x servers. It does this by copying NetWare account information to the primary domain controller (PDC) and then propagating changes back to the bindery on the NetWare servers. DSMN also synchronizes accounts across all NetWare servers allowing users to access any NetWare server using a single logon username. DSMN does not come with Windows 2000 but can be ordered separately from your Microsoft value-added reseller (VAR).

Notes

DSMN supports NetWare 4.x servers only when they are running in bindery emulation mode, not in Novell Directory Services (NDS) mode.

Directory Service Markup Language (DSML)

A specification based on XML (Extensible Markup Language) that enables different directory applications to share information.

Overview

Directory Service Markup Language (DSML) is a markup language (such as Hypertext Markup Language [HTML]) whose function is to allow directory information to be represented using XML. Its purpose in doing this is to make XML the common language for exchange of information between different directory systems.

DSML is an open specification, and its membership includes Microsoft, IBM, Novell, and Oracle. A draft standard is being developed by the Organization for the Advancement of Structured Information Standards (OASIS).

Implementation

DSML is essentially a set of extensions to XML that is expressed as a schema. The DSML schema for XML provides mechanisms for accessing information in

Directories even if the actual format of the data is unknown. Using a set of tags specific to directory services, DSML allows information in one proprietary directory to be exchanged with another proprietary directory without the need to pay attention to the mechanics happening underneath or how the directories operate.

The original DSML 1 specification was limited to specifying how to use XML to describe a directory's contents. The newer DSML 2 specification adds standard mechanisms for using XML to locate, access, and manipulate information stored in directories. Using DSML 2, developers will be able to build transactional applications that use XML to find and modify objects stored in a directory, regardless of the vendor from which the directory is obtained.

Notes

A related initiative is the Directory Interoperability Forum (DIF), whose aim is to establish a standard that will enable use of the Lightweight Directory Access Protocol (LDAP) for performing data queries across multiple directories. DSML and DIF are separate initiatives, but they might eventually merge or be subsumed within a wider objective.

Directory Service Migration Tool (DSMigrate)

A tool for migrating information from Novell NetWare networks to Microsoft Windows 2000.

Overview

Directory Service Migration Tool (DSMigrate) is a tool that you can use to migrate NetWare users, groups, files, and permissions to Active Directory directory service. DSMigrate can migrate both bindery-based NetWare 3.x servers and Novell Directory Services (NDS)–based NetWare 4.x and 5.x servers to Windows 2000.

DSMigrate lets you perform a test migration to assess any difficulties that might occur before you perform your final migration. DSMigrate is one of the NetWare tools included with Windows 2000.

directory synchronization (Microsoft Mail)

The process by which information stored in Microsoft Mail 3.x mail systems is replicated between postoffices.

Overview

There is only one directory server postoffice in a Microsoft Mail 3.x mail system; other postoffices that participate in directory synchronization are called requestor postoffices. Requestor postoffices send their address list updates to the directory server postoffice, which then sends cumulative changes back to the requestor postoffice. Directory synchronization also ensures that the global address list is updated.

When migrating legacy MS Mail systems to Microsoft Exchange Server, establishing directory synchronization between the old MS Mail directory and the new Exchange directory is a typical step in the process. To make this possible, Microsoft Exchange includes a dirsync component that emulates the MS Mail directory until the old directory information can be entirely migrated to the new system.

See Also: [Exchange Server](#)

directory synchronization (Windows NT)

The process of directory synchronization within a Microsoft Windows NT domain.

Overview

Directory synchronization is the process whereby the domain directory databases of backup domain controllers (BDCs) in a Microsoft Windows NT domain are synchronized with the master directory database on the primary domain controller (PDC). Accurate and reliable directory synchronization is the foundation for effective operation of Windows NT Directory Services (NTDS).

In Windows 2000 and Windows .NET Server, this process of replicating directory information between domain controllers is called directory replication.

Notes

If directory synchronization must be performed over slow wide area network (WAN) links, you can adjust

some registry parameters to make directory synchronization more efficient and prevent it from consuming excessive bandwidth.

Direct Sequence Spread Spectrum (DSSS)

A combination of two transmission technologies (direct sequencing and spread spectrum) used in wireless networking and cellular communications.

Overview

Direct Sequence Spread Spectrum (DSSS) is the most popular transmission scheme used in wireless networking and is widely deployed in cellular communications systems also. DSSS is the basis of the 802.11b wireless local area network (LAN) standard used around the world.

Implementation

DSSS transmits data 1 bit at a time. Each bit is processed by modulating it against a pattern called a chipping sequence. For example, in 802.11b the chipping sequence is an 11-bit binary sequence 10110111000 called the Barker code. This sequence is chosen as it has certain mathematical properties that make it suitable for modulation of radio waves. The sequence is exclusively ORd (XORd) with each bit of the data stream, which has the effect of multiplying the number of bits transmitted by a factor of 11 (each 11-bit transmission is called a “chip” and represents only a single bit of actual data). While this seems wasteful in terms of bandwidth, it has the advantage that if some of the transmitted bits are lost, the original data stream can still be reliably reconstructed by processing the remaining information. This feature, in addition to spread spectrum transmission, which sends the data over multiple frequencies simultaneously, makes DSSS strongly resistant to interference due to extraneous radio sources, multipath reflection, and atmospheric conditions.

See Also: *802.11b, cellular communications, direct sequencing, spread spectrum, wireless networking*

direct sequencing

A transmission method used for wireless networking.

Overview

Direct sequencing systems transmit data one bit at a time. Each bit of data is then transmitted simultaneously over a range of frequencies.

Direct sequencing. *How direct sequencing works.*

Direct sequencing is usually used in conjunction with spread spectrum, a transmission method where the data transmitted is spread over multiple frequencies to reduce signal loss due to noise and interference. The transmitter feeds each bit of the data stream into a signal spreader that multiplies the input, creating a wideband signal. The wideband signal is then amplified and broadcast by using an antenna.

Uses

Direct sequencing can be used for both wireless local area network (LAN) connections and as part of a cellular telephone system. Direct sequencing has a faster theoretical maximum data transmission rate than frequency hopping, another wireless transmission method, but in practice both methods provide similar throughput for wireless transmission of data because of protocol overhead in typical wireless communication systems.

disaster recovery

The process of recovering IT (information technology) operations after a failure or disaster.

D

Overview

D Because IT is the lifeblood of today's e-business economy, it is essential to be able to recover IT operations quickly after a disaster. An IT disaster can be something as small as a failed disk drive within a server or something as big as a data center burning to the ground. Other common examples of disasters include power failures, destruction due to viruses, theft, sabotage, accidental commands issued by administrators that result in files being deleted or modified, earthquakes, insurrections, and so on. Being prepared for eventualities such as these is the responsibility of IT management and is critical to the success of modern businesses.

The key to successful recovery from these situations is a comprehensive, tested disaster recovery plan. This is a business plan that involves not just redundant hardware but personnel, procedures, responsibilities, and issues of legal liability.

Implementation

The first step in such a plan involves risk assessment to determine which components are most vulnerable and how the company can function in response to loss of data or critical IT services. It is also important to determine what is acceptable to management in terms of a recovery window—many businesses today would suffer significant loss if it should take more than a day or two to recover from failed systems.

Disaster recovery plans can be implemented in different ways depending on the size and needs of the company involved. Three common approaches to implementing disaster recovery plans are traditional tape backup, e-vaulting, and mirroring.

The traditional approach of small to mid-sized businesses to disaster recovery is to create full backups to tape daily and archive these tapes off-site in secure locations. Most computer systems in businesses use this method, primarily due to its low cost and its well-known procedures. However, tape backups must be verified, and test restores must be performed periodically to ensure that this system is in fact working. Furthermore, businesses must realize that it typically takes up to 48 hours to restore a failed disk or system from tape

backup, a recovery window that may be unacceptable from an e-business standpoint.

E-vaulting (or electronic vaulting or data vaulting) takes a different approach. Instead of archiving data to tape, it is sent over high-speed leased lines or Internet connections to a remote data center for safe storage. E-vaulting makes it possible to do more frequent backups and rapid restores, but the weak link is the wide area network (WAN) connection, for if that goes down, a restore might be difficult or impossible.

To make e-vaulting more effective, companies sometimes arrange for backup servers to be running at the remote site and back up data directly to those servers. Then if a failure occurs with the company's main servers, control can be switched over to the backup servers and business can continue without interruption. The problem is that having duplicate systems in place is an expensive proposition and complex to manage, and companies often try to save money by placing older hardware at the remote site. When disaster strikes, this hardware may not be able to perform as hoped and business will go down.

Another version of e-vaulting involves using a mobile data center (a network in a moving van) at the remote site. When disaster strikes the primary site, the mobile data center can be brought on location and managed by your staff.

Regardless of which form of e-vaulting is used, the main disadvantage in the eyes of most companies is the cost, which is typically many times that of using traditional tape backup solutions.

Extending the idea of e-vaulting is a method called mirroring, in which identical hardware is placed at a remote site and data is kept synchronized between servers in the primary and remote site. This is a costly solution both from the point of view of the redundant hardware required and the throughput needed for WAN links, but the restore window is typically under an hour when disaster strikes, so it is a good option from the perspective of e-businesses. Financial institutions such as banks and credit unions often employ this solution to ensure maximum availability and reliability for customer access to accounts.

Marketplace

While smaller companies tend to manage their own tape backup and e-vaulting solutions in-house, large enterprises generally outsource their disaster recovery needs, particularly if mainframe systems and AS/400s are involved. Three companies handle the lion's share of disaster recovery business at the enterprise level: Comdisco Continuity Services, SunGard Recovery Services, and IBM's Business Continuity Recovery Services (BCRS).

E-vaulting companies abound and their range of services varies greatly. One example of such a company is Imation, which offers its LiveVault services for small and medium-sized companies.

Businesses that host their business services with Web hosting companies often make use of disaster recovery services provided by these services. An example is Exodus Communications, which provides mirroring services for customers at remote data centers.

discrete multitone (DMT)

A line coding technique used in Asymmetric Digital Subscriber Line (ADSL).

Overview

Discrete multitone (DMT) describes a specification for the physical layer transport for ADSL and is an efficient mechanism for transmitting data at high speeds at frequencies above the voice cutoff on ordinary copper phone lines. DMT offers good performance and resistance to crosstalk and electromagnetic interference, and it can be used to dynamically adapt data flow to line conditions. DMT is the most popular ADSL line coding scheme in use today.

History

DMT was developed by Bellcore in 1987 as a line coding scheme of Asymmetric Digital Subscriber Line (ADSL) services. DMT evolved from V.34 modem technology and was first commercially implemented in ADSL modem technology by Amati Corporation. At the time, DMT was one of several line coding schemes that had been proposed by carriers offering ADSL ser-

vices. Another competing scheme used was carrierless amplitude phase modulation (CAP), which is based on quadrature amplitude modulation (QAM). But while CAP was more widely deployed initially in ADSL roll-outs, DMT was adopted by standards bodies in the United States and Europe and is supported by the International Telecommunication Union (ITU).

Implementation

CAP employs a band of frequencies from 40 kilohertz (KHz) to 1.1 megahertz (MHz), well above the 4 KHz cutoff for voice transmission over the copper local loop. CAP divides this band into 4 KHz wide channels, with each channel being modulated independently and all of them simultaneously carrying data in parallel. An ADSL modem that uses CAP can thus be thought of as a collection of hundreds of tiny modems operating in parallel.

Each CAP channel can carry up to 15 bits/symbol/hertz (Hz) of information, using QAM as a modulation scheme (actual throughput per channel may be less due to electromagnetic interference and other conditions). Upstream transmission uses 25 channels giving a maximum throughput of

$25 \text{ channels} \times 15 \text{ bits/symbol/Hz} \times 4 \text{ KHz} = 1.5 \text{ Mbps}$

while downstream uses 249 channels giving a maximum throughput of

$249 \text{ channels} \times 15 \text{ bits/symbol/Hz} \times 4 \text{ KHz} = 14.9 \text{ Mbps}$

discretionary access control list (DACL)

An access control list (ACL) that can be configured by administrators.

Overview

In Microsoft Windows 2000, Windows XP, Windows .NET Server, and Windows NT, a discretionary access control list (DACL) is an internal list attached to a file or folder on a volume formatted using the NTFS file system (NTFS). The administrator can configure the DACL, and it specifies which users and groups can

perform different actions on the file or folder. In Windows 2000, Windows XP, and Windows .NET Server, DACLs can also be attached to objects in Active Directory directory service to specify which users and groups can access the object and what kinds of operations they can perform on the object.

Implementation

In Windows 2000 and Windows .NET Server, each object in Active Directory or file on a local NTFS volume has an attribute called Security Descriptor that stores information about the following:

- The object's owner (the security identifier or the owner) and the groups to which the owner belongs
- The DACL of the object, which lists the security principals (users, groups, and computers) that have access to the object and their level of access
- The system access control list (SACL), which lists the security principals that should trigger audit events when accessing the list

The DACL for an object specifies the list of users and groups who are authorized to access the object and also what levels of access they have. The kinds of access that can be assigned to an object depend on the type of object under consideration. For example, a file object can have read access assigned to a user but a printer object cannot. (You cannot read a printer!)

The DACL for an object consists of a list of access control entries (ACEs). A given ACE applies to a class of objects, an object, or an attribute of an object. Each ACE specifies the security identifier (SID) of the security principal to which the ACE applies, as well as the level of access to the object permitted for the security principal. For example, a user or group might have permission to modify all or some of the attributes of the object, or might not even have permission to be aware of the object's existence. In common parlance, DACLs are sometimes simply referred to as access control lists or ACLs, although this is not strictly correct.

Notes

The owner of an object always has permission to modify its DACL by granting permissions to other users and groups.

disk duplexing

Disk mirroring using separate disk controllers.

Overview

Disk duplexing is a fault-tolerant disk technology that is essentially the same as disk mirroring, except that a separate disk drive controller is used for each mirrored drive. Disk duplexing thus provides two levels of fault tolerance:

- If one drive fails, the other contains a mirrored copy of the data.
- If one controller fails, the other controller continues to function.

Advantages and Disadvantages

Besides the additional level of fault tolerance, disk duplexing also provides slightly better read and write performance than disk mirroring because the two controllers provide two separate channels for data transmission. The down side is that disk duplexing is more expensive than disk mirroring since an extra controller card is required.

Microsoft Windows 2000, Windows XP, Windows .NET Server, and Windows NT Server support disk duplexing. You establish disk duplexing on Windows NT systems at the partition level and on Windows 2000, Windows XP, and Windows .NET Server at the volume level. In terms of system recovery and management, there is no difference between disk mirroring and disk duplexing.

See Also: *disk mirroring, fault tolerance, redundant array of independent disks (RAID)*

disk imaging

A method for creating an exact duplicate of the software installed on a computer system.

Overview

Disk imaging (also called cloning) is frequently used in enterprise environments as a way of rapidly deploying workstations (and occasionally servers) on a network. The first step in disk imaging is to create the reference system, a computer that has its operating system and applications installed and configured exactly as desired. A snapshot or image of this system is then taken using disk imaging software, and the image is stored on a server on the network. Agent software is then used to boot fresh systems (that is, computers with no operating system installed), connect to the server, download the image, and recreate it bit for bit on the new systems. The resulting systems are exact duplicates of the reference system.

Advantages and Disadvantages

Disk imaging is a much faster way of installing operating systems and applications on machines than the traditional methods of running setup programs. A traditional installation of an operating system and suite of applications might take hours—disk imaging often takes only a few minutes.

The downside of the process is that disk imaging is usually successful only when the cloned machines have the exact same hardware configuration as the reference machine. Nevertheless, disk imaging is a speedy and easy way to roll out large numbers of identical workstations and has become widely popular among enterprise administrators.

One further issue that must be considered is licensing—before using disk imaging to roll out a network, make sure that the operating system vendor supports this operation and that it does not violate your licensing agreement.

Marketplace

One of the earliest and still popular disk imaging applications is Ghost from Symantec Corp. In fact, disk imaging is often referred to as “ghosting” in reference to this product’s impact on the industry. Other popular tools include ImageCast IC3 from Innovative Software, DriveImage from PowerQuest Corporation, and RapiDeploy from Altiris.

disk mirroring

A fault-tolerant disk technology that employs two drives having identical information on them instead of just one.

Overview

In disk mirroring, both drives are controlled by the same disk controller, and when data is written to the controller, it is copied to both drives. Disk mirroring thus provides a measure of fault tolerance for disk subsystems, since if one drive in the mirror set fails, the other contains an up-to-date copy of all the data and can immediately take over without interruption of services.

Advantages and Disadvantages

In addition to fault tolerance, disk mirroring also provides better write performance than RAID-5 systems. On the other hand, disk mirroring read performance is worse than RAID-5 (though better than for a single disk).

Microsoft Windows 2000, Windows XP, Windows .NET Server, and Windows NT Server support disk mirroring. You establish disk mirroring on Windows NT systems at the partition level and on Windows 2000, Windows XP, and Windows .NET Server at the volume level. A more fault-tolerant form of disk mirroring is disk duplexing, which is discussed in its own article elsewhere in the book.

Diskperf command

A Microsoft Windows NT, Windows 2000, Windows XP, and Windows .NET Server command for starting and stopping disk performance counters for Performance Monitor (System Monitor in Windows 2000, Windows XP, and Windows .NET Server).

Overview

Counters for the objects Logical Disk (partition) and Physical Disk (drive) are disabled by default because a performance hit of a few percent can occur if they are enabled. You must run the Diskperf command prior to monitoring disk activity with Performance Monitor. On some disk subsystems, enabling these counters might produce a small decrease in system performance, so you should disable them when monitoring of the system is completed. You must reboot the system after running Diskperf.

Diskperf -n sets the system to not use any disk performance counters.

For the full syntax of this command, type **diskperf /?** on the command line.

disk quotas

A mechanism for managing how much data users can store on disks.

Overview

Disk quotas are a feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that administrators can use to track and control disk usage on a per-user basis for each NTFS file system (NTFS) volume that the user stores data on. Support for disk quotas is built into the new version of NTFS on Windows 2000, Windows XP, and Windows .NET Server.

Disk quotas are tracked independently for each NTFS volume even if several volumes are on the same physical disk. For purposes of managing disk quotas for users, disk space usage is based on file and folder ownership. Windows 2000, Windows XP, and Windows .NET Server ignore compression when it calculates how much disk space a user is utilizing. Whatever is unallocated in a user's disk quota is reported as free space for applications that allow the user to access disk space.

Depending on how disk quotas are configured, when a user exceeds the specified disk limit, one of two things can occur:

- An event is logged to the system log.
- Disk access is blocked and an event is logged. The user is presented with an “insufficient disk space” error.

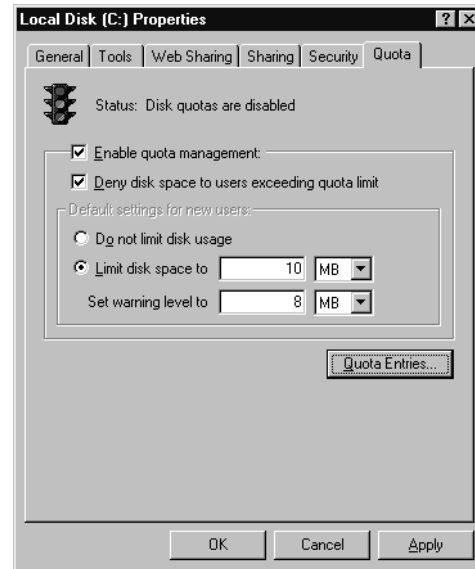

Implementation

To use disk quotas on an NTFS volume, you must first enable this feature when the volume is created and before any users have access to it. Typically, you will begin by setting more restrictive settings for all users, and then relax these settings for users who need more disk space or work with large files.

To enable disk quotas, set quota limits, and specify what happens when users exceed their quotas, use the Quota tab

on the property sheet for an NTFS volume. To configure disk quotas for users, you essentially specify two values:

- **Quota limit:** How much disk space the user is allowed to use
- **Quota threshold:** The conditions under which an event should be logged to indicate that the user is nearing his or her quota limit

Disk quotas. Configuring disk quotas in Windows 2000.

For example, if the quota limit for a user is set to 10 megabytes (MB) while the quota threshold is specified as 8 MB, an event is logged when the user stores more than 8 MB of data on the volume, and the user is prevented from storing more than 10 MB of data on the volume.

To view the status of disk quotas on an NTFS volume for which this feature has been enabled, open the volume's property sheet and examine the traffic light icon. The light is

- Red if quotas are disabled
- Yellow if the NTFS file system is recalculating the status of quota compliance
- Green if quotas are enabled

If you want to track disk usage by user but do not want to deny users access to a volume, you can enable disk quotas but specify that users can exceed their disk quota

limit. Note also that enabling disk quotas incurs slight overhead in file system performance.

disk status

Information about whether a disk is healthy or has a problem.

Overview

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, disk status is displayed in the Disk Management portion of the Computer Management console. The Status column shows the status indicators according to the following table. The letter *B* here indicates that the status indicator can apply to basic disks, and *D* indicates dynamic disks.

Disk Status

Disk Status	Description/Prescription
Online (BD)	The disk is accessible. There are no problems.
Online—Errors (D)	I/O errors detected. Try reactivating the disk to see whether the errors are transient.
Offline (D)	The disk is not accessible and might be corrupted, disconnected, or powered down. Try reactivating the disk, and check the cables and the controller.
Foreign (D)	The disk has been moved to this machine from another computer running Windows 2000 (same for Windows XP and Windows .NET Server). You must import the foreign disk before you can use it.
Unreadable (BD)	The disk is not accessible and might be corrupted, have I/O errors, or hardware failure. Try rescanning the disk or rebooting the system to see whether it recovers.
Unrecognized	The disk type is unknown, and the disk is probably from a different operating system, such as UNIX.
No Media	The drive is either a CD-ROM drive or some type of removable drive and has no media in it.

Distance Vector Multicast Routing Protocol (DVMRP)

A multicast routing protocol based on the spanning tree algorithm.

Overview

Distance Vector Multicast Routing Protocol (DVMRP) is one of three routing protocols used for multicast routing, the other two being Protocol Independent Multicast Dense Mode (PIM-DM) and Multicast Open Shortest Path First (MOSPF). DVMRP is used for dense mode multicasting where the hosts receiving the multicast are densely congregated in large pockets of the network. DVMRP assumes that all hosts on connected subnets want to receive the multicast. A typical scenario where DVMRP might be used would be for webcasting sports events, concerts, or corporate presentations.

Implementation

DVMRP floods the network with multicast packets to try to get information out as rapidly as possible to the furthest corner of the network. DVMRP assumes that there is sufficient bandwidth to support this operation. Once a multicast session is established, DVMRP then prunes the routing tree by cutting off multicasts to routers whose connected networks have no hosts receiving them. If a router determines using Internet Group Membership Protocol (IGMP) that no downstream hosts or routers require the multicast transmission, it contacts the upstream DVMRP router and asks to be removed from its list for the multicast session.

DVMRP routers check their routing tables frequently to determine the optimal route to nearby DVMRP routers. DVMRP uses broadcasts to keep routing tables up to date, which tends to consume a lot of network bandwidth. As a result, DVMRP should only be implemented on connections that have sufficiently high bandwidth to support it.

distance vector routing algorithm

A routing algorithm used by certain types of routing protocols.

D

Overview

Also called the Bellman-Ford algorithm after its originators, the distance vector routing is an algorithm designed to enable routers to maintain up-to-date information in their routing tables. The main alternative to distance vector routing is link state routing, which is discussed in its own article elsewhere in this book.

Implementation

Using the distance vector method, each router on the internetwork maintains a routing table that contains one entry for each possible remote subnet on the network. To do this, each router periodically advertises its routing table information to routers in adjacent subnets. Each routing advertisement contains the following information about each route in that routing table:

- The metric (hop count) for the route, which indicates the distance to the remote subnet
- The vector (direction) in which the route is located

These router advertisements are performed independently by all routers (that is, no synchronization exists between advertisements made by different routers). In addition, routers receiving advertisements do not generate acknowledgments, which reduces the overhead of routing protocol traffic.

Routers select the route with the lowest cost to each possible destination and add this to their own routing tables. Routers in adjacent subnets then propagate this information to more distant subnets hop by hop until information from all routers has spread throughout the entire internetwork and convergence (agreement between routing tables on all routers in the internetwork) is attained. The end result is that each router on the network is aware of all remote subnets on the network and has information concerning the shortest path to get to each remote subnet.

Uses

The Routing Information Protocol (RIP), which is supported by Microsoft Windows 2000, Windows XP, and

Windows .NET Server, is one example of a dynamic routing protocol that uses the distance vector routing algorithm. Other examples are described in the article “distance vector routing protocol” elsewhere in this chapter.

Advantages and Disadvantages

Distance vector routing protocols (that is, protocols based on the distance vector routing algorithm) are generally simpler to understand and easier to configure than link state routing algorithm protocols. To configure a router that supports distance vector routing, you basically connect the interfaces to the various subnets and turn the router on. The router automatically discovers its neighbors, which add the new router to their routing tables as required.

The main disadvantage of the distance vector routing algorithm is that changes are propagated very slowly throughout a large internetwork because all routing tables must be recalculated. This is called the Slow Convergence Problem. When convergence is slow, it is possible that routing loops can temporarily form, which forward packets to black holes on the network, causing information to be lost. Most distance vector routing protocols implement use a technique such as the split horizon method to ensure that the chances of routing loops being formed are extremely small.

Another disadvantage of distance vector routing is that routing tables can become extremely large, making distance vector routing protocols unsuitable for large internetworks, and that route advertising generates a large amount of traffic overhead.

As a result of these issues, distance vector routing is generally best used in internetworks having 50 routers or fewer and in which the largest distance between two subnets is less than 16 hops. Despite these limitations, distance vector routing protocols are more popular than link state routing protocols, mainly because they are easier to set up and maintain (everything is automatic) and because their CPU processing requirements are small, which allows such protocols to be implemented on low-end and mid-end routers.

distance vector routing protocol

Any routing protocol that is based on the distance vector routing algorithm.

Overview

The most popular routing protocols based on the distance vector routing protocol are

- **RIPv1 (Routing Information Protocol version 1):** This is a classful routing protocol that is suitable for small to mid-sized internetworks. RIPv1 supports both Internet Protocol (IP) and Internetwork Packet Exchange (IPX) routing.
- **RIPv2:** This is a newer version of RIP that supports variable length subnet masks (VLSMs).
- **IGRP (Interior Gateway Routing Protocol):** This is an interior gateway protocol (IGP) that uses a combination of different metrics for more efficient routing. IGRP was designed by Cisco Systems and is a proprietary routing protocol.
- **RTMP (Routing Table Maintenance Protocol):** This routing protocol is used in AppleTalk networks.

Advantages and Disadvantages

Distance vector routing protocols have some advantages over link state routing protocols: they are easier to configure and manage and their router advertisements are easier to understand and troubleshoot. On the other hand, distance vector routing protocols often have much larger routing tables, greater overhead of router traffic, long convergence times, and they scale poorly. As a result, they are most often used for small to mid-sized internetworks.

distinguished name (DN)

A method for uniquely naming objects within a directory.

Overview

Distinguished names (DNs) are part of the X.500 directory specifications and are used for locating and accessing objects using the Lightweight Directory Access Protocol (LDAP), and directories based on the X.500 or LDAP specifications are hierarchical in structure. For example, in an LDAP directory, the root or top node is a container that contains child nodes that can be either leaf nodes (end nodes) or containers themselves. An object that is a leaf node has a common name (CN) that identifies it, but this common name is not necessarily unique. By including with the common name the names of the root node (o node) and any containers and subcontainers (ou nodes) along the branch to the leaf node, a unique name can be constructed for the leaf node. This unique name is called the DN and is unique to the entire directory.

The DN for an object is thus formed by concatenation of the common name or relative distinguished name (RDN) of the object together with the names of each ancestor of the object all the way to the root object of the directory. As a result, if an object is renamed or moved to another container within a directory, its DN changes. Since this is undesirable from the point of view of applications accessing a directory, real-life directories such as Microsoft Corporation's Active Directory directory service use an internal naming scheme for objects that is invariant under object renames and moves (Active Directory uses globally unique identifiers [GUIDs] for internally naming objects).

Examples

DNs are one of the addressing formats for objects within Active Directory in Microsoft Windows 2000. In Active Directory, every object in the directory requires a unique name. Several kinds of names can be used to define a specific object in Active Directory, including

- **Distinguished name (DN):** This specifies the complete path to the object through the hierarchy of containers.
- **Relative distinguished name (RDN):** This is the portion of the distinguished name that is an attribute of the object itself.

- **User principal name (UPN):** This is the name used when a user logs on to the network.

D

For example, let's consider a User object within Active Directory. A User object is an example of a leaf object because it cannot contain other objects. User objects such as Jeff Smith are identified using CNs. A container is a directory object that can contain other objects. In Active Directory, containers are referred to as organizational units (OUs) because they are used to organize other objects into hierarchies of containers. For example, the user Jeff Smith would typically be contained within the Users container. At the top of the container hierarchy are the containers that represent different components of the domain itself. These components are called domain components (DCs). For example, if user Jeff Smith exists in the microsoft.com domain, the DN for this user is represented by the path DC=com,DC=microsoft,OU=Users,CN=Jeff Smith.

In Microsoft Exchange Server 5.5, which used its own proprietary directory instead of Active Directory, DNs were also used to identify recipients. Exchange automatically creates a DN for every recipient object in its directory database, including objects such as mailboxes, distribution lists, and public folders. For example, if a user Jeff Smith has a mailbox named JeffS located on an Exchange server in Redmond at the organization Microsoft, the DN for this user would be represented internally as O=Microsoft,OU=Redmond,CN=Recipients,CN=JeffS.

The Message Transfer Agent (MTA) uses a recipient's DN to determine how to route messages to that recipient within an Exchange organization.

distributed application

An application consisting of two or more parts that run on different machines but act together seamlessly.

Overview

In the simplest example of a distributed application, the user interface portion runs on a client machine while the

processor- or storage-intensive portion runs on a server. This type of distributed application is called a client/server application. Examples of client/server applications include the following:

- Microsoft Exchange Server (back end) as a mail server with users running Microsoft Outlook (front end) on their client machines
- Microsoft Access (front end) as an interface for accessing database information stored in Microsoft SQL Server (back end)
- A Web application written using Active Server Pages (ASP) for Internet Information Services (IIS) (back end) that is accessed from a client machine running Microsoft Internet Explorer (front end)

In a more complex scenario, three tiers are used to create a distributed application. The back end may be an SQL database containing customer or sales information. The front end might be a simple Web browser, used by the employee to request sales information from the database. The middle tier of the distributed application would be the Web application running on an IIS machine.

Distributed Component Object Model (DCOM)

A Microsoft programming technology for developing distributed applications.

Overview

Distributed Component Object Model (DCOM) is a Microsoft technology developed in 1996 for component-based development of software that is network-aware. Using DCOM, developers can create network-aware applications using Component Object Model (COM) components. DCOM works under various network transports, including Transmission Control Protocol/Internet Protocol (TCP/IP), and is basically a set of extensions to COM. DCOM is the preferred method for building client/server applications in Windows 2000, Windows XP, and Windows .NET Server, and it was formerly known as Network OLE.

Implementation

DCOM functions as a client/server protocol that provides distributed network services to COM, allowing DCOM-enabled software components to communicate over a network in a similar fashion to the method by which COM components communicate among themselves on a single machine. DCOM client objects make requests for services from DCOM server objects on different machines on the network using a standard set of interfaces.

Distributed Component Object Model (DCOM). How DCOM works.

The client object cannot call the server object directly. Instead, the operating system intercepts the DCOM request and uses interprocess communication mechanisms such as remote procedure calls (RPCs) to provide a transparent communication mechanism between the client and server objects. The COM run time provides the necessary object-oriented services to the client and server objects. The COM run time also uses the security provider and RPCs to create network frames that conform to the DCOM standard.

In Microsoft Windows 2000, DCOM requests are sent using RPCs. Windows 2000 use security features such as permissions to enable software components to securely and reliably communicate over the network.

distributed computing

A programming model that distributes processing across a network.

Overview

The architecture of programming applications has gone through several evolutionary steps over the last few decades. The original mainframe computing model had all the processing done centrally on the mainframe, with dumb terminals used for input and displaying results. The next evolutionary step was client/server computing where the client and server shared different aspects of the processing. Applications had to be specially tailored to take advantage of the client/server processing model. Recently a three-tier model has become dominant, which augments the client/server paradigm with a middle tier that encapsulates business logic in programming constructs.

The next evolutionary step in business computing is the distributed computing model. In distributed computing, there is no single centralized server. Instead, network communications are used to connect servers, clients, handheld devices, and other smart devices into a processing fabric. The different components of this fabric may be scattered widely across a network.

Microsoft Corporation's new .NET platform is designed to maximize processing gains through implementing a distributed computing model for building Web services and applications. Distributed computing is poised to revolutionize business services and how they are developed, and .NET supports peer-to-peer (P2P) computing as one manifestation of its distributed computing model.

Distributed Denial of Service (DDoS)

A type of denial of service (DoS) attack that employs a large number of intermediate hosts to multiply the effect of the attack.

Overview

Although a DoS attack typically uses the attacker's machine or group of machines to launch it, a DDoS attack uses unwitting third-party hosts instead. The result can be devastating if hundreds—or thousands—of machines are involved.

Distributed Denial of Service (DDoS). How a DDoS attack works.

To launch a DDoS attack against a specific Web server, an attacker first finds a vulnerable network and installs DDoS tools on hundreds or even thousands of hosts on that network. Common tools used include Tribe Flood-Net (TFN), TFN2K, trino, Stacheldraht, and many others easily downloaded from locations on the Internet. These compromised hosts become “zombies” under the attacker’s control (other terms used to describe them include agents, daemons, or DDoS servers). Linux and Solaris systems have been the most popular systems exploited as zombies so far. A good indicator that an attacker might be trying to compromise your network by installing DDoS tools on hosts is a sudden increase in Rcp (remote copy protocol) traffic, which is often used to install these tools remotely. This kind of activity can be detected by a network intrusion detection system (firewall logs are less help, as attackers usually compromise a single host on the network and then use Rcp to install the tools on other hosts internally on the network from that point on).

Once the intermediate network is compromised and tools installed, the attacker launches the attack using a remote management console, and the zombies then attack the target host using a DoS attack method such as synchronous idle character (SYN) flooding, User Datagram Protocol (UDP) flooding, a smurf attack, or Internet Control Message Protocol (ICMP) flooding. The attack is usually overwhelming, usually bringing down the targeted server and often saturating the target’s network so that other servers on the network are unable to communicate as well. Address spoofing is used to make it difficult to trace the machines launching the attack, and even if these zombies are identified, it is usually even more difficult to trace the single machine from which the attacker is managing the attack. An even more insidious version of DDoS makes it even harder to track the attacker by employing another layer of intermediate machines called masters, which are controlled by the attacker’s management console and which themselves control the zombies. A master is typically the first host compromised on an intermediate network, and a full-scale DDoS attack may employ dozens of

intermediate networks, each with their own master and hundreds of zombies.

Prospects

The most famous DDoS attack was instituted by Mafiaboy, a Canadian teenager who allegedly brought down a number of major Web sites for hours in February 2000, including Amazon.com, Buy.com, CNN.com, eBay, E-Trade.com, Yahoo!, and ZDNet. The attack was performed using tools that are easily downloadable from a number of sites on the Internet.

There is still no simple solution for protecting sites against DDoS attacks. The main problem is the large number of networks connected to the Internet that are poorly secured and are open to exploitation for using their machines as zombies for launching DDoS attacks on other, better-secured sites. Lack of vigilance on the part of the administrators of these vulnerable networks thus affects the success of everyone's sites on the Internet. Omissions such as allowing directed inbound broadcasts to networks and failing to implement ingress and egress filtering properly on routers on a network's border are typical mistakes by administrators that render corporate networks vulnerable to hijacking for performing DDoS attacks.

One step forward was the establishment in 2001 of the Information Technology Information Sharing and Analysis Center (ITISAC) by the U.S. Department of Commerce. ITISAC is designed to help companies share information about DDoS attacks to better defend against them. Another issue is the impending prospect of organizations being held liable for their poorly secured corporate networks should hackers establish zombies on these networks and use them to launch DDoS attacks against other sites. The Internet Engineering Task Force (IETF) is also involved and has established a working group RFC 2267+ to help strategize on the best way to deal with DDoS attacks. Despite these initiatives, the Internet remains vulnerable to such attacks and will likely continue to be so for the immediate future.

Distributed file system (Dfs)

A network file system that makes many shares on different file servers look like a single hierarchy of shares on a single file server.

Overview

Distributed file system (Dfs) is a feature of the Microsoft Windows 2000 and Windows .NET Server operating systems and a separately available add-on for the Windows NT operating system. Dfs allows file servers and network shares to be logically organized into a single Dfs directory tree. This simplifies management of network resources and makes it easier for users to locate and access network resources. From the user's perspective, Dfs makes it appear that there is only one server containing a hierarchical tree of resources, while in fact these resources might be distributed across multiple servers in different locations.

Dfs simplifies directory browsing, offers search tools that simplify locating network resources, and offers administrative tools for building and managing Dfs directory trees. It also eliminates the need for Windows 95, Windows 98, or Windows NT Workstation clients to form multiple persistent network connections because users require only one persistent connection to the directory tree.

Implementation

In the Windows 2000 and Windows .NET Server implementation, you first open the Dfs snap-in for Microsoft Management Console (MMC) to create a Dfs root node. You can then create Dfs child nodes under the root node. Each child represents a shared folder that can be located anywhere on the network. When users want to access a resource on the network, they navigate through the Dfs tree and do not need to know the particular server the resource is located on. Users must have Dfs client software installed on their machines. Dfs client software is included with Windows 2000, Windows XP, Windows .NET Server, Windows NT, and Windows 98. An optional Dfs client can be downloaded for Windows 95 from the Microsoft Web site.

You can configure Dfs to operate in two ways:

- **Stand-alone Dfs:** This type of Dfs stores the description of the Dfs file system topology on a

D

single computer. If that computer fails, the entire Dfs system goes down, although users can still access resources the traditional way using mapped network drives or Universal Naming Convention (UNC) paths if they know which servers these resources are stored on and the names of the shares.

- **Fault-tolerant Dfs:** This type of Dfs stores the Dfs topology information in Active Directory directory service on Windows 2000 and Windows .NET Server domain controllers. This configuration is better for fault tolerance and file replication.

Notes

If a server containing Dfs shares fails, you can simply move the files to another machine, create new shares, and map the existing Dfs child nodes to the new shares. Your users will not even know that anything has changed. If you assign a user permission to access a shared folder, that person automatically has permission to access it through the Dfs tree as well.

Distributed Management Task Force (DMTF)

An industry consortium that develops specifications for cross-platform management standards.

Overview

The Distributed Management Task Force (DMTF) is a consortium of industry players that are developing specifications and standards for managing disparate systems using a common and ubiquitous tool, the Web browser. The DMTF was formerly known as the Desktop Management Task Force, and it has the support of most major networking and operating system vendors.

The DMTF has been working on several initiatives since its inception in 1996:

- **Web-Based Enterprise Management (WBEM):** A set of standards for developing systems to manage networks and systems using simple Web browsers.
- **Common Information Model (CIM):** A set of schema for describing information collected for network and systems management purposes.

- **Directory Enabled Networking (DEN):** A specification for how to store network and systems management information in a directory.

A complementary set of standards for cross-platform network and system administration is being developed by the Internet Engineering Task Force's (IETF) Policy Framework Working Group.

Notes

Windows Management Interface (WMI) is Microsoft Corporation's implementation of the DMTF'S WBEM architecture. WMI is a core feature of the Microsoft Windows 2000, Windows XP, and Windows .NET Server operating system platforms.

distribution box

A fixed or freestanding miniature patch panel in an enclosure.

Overview

Typically, horizontal cable runs are connected to the punchdown blocks within the distribution box, and drop cables are plugged into the RJ-45 ports of the box. You can thus use distribution boxes to provide central cabling points away from walls. Stations can then be plugged and unplugged from an accessible location in the work area instead of from the back of the workstations (after you bend down and crawl behind the machine) or from the land drops in the wall (which are often hidden behind desks or other obstacles).

Uses

Use distribution boxes for classrooms and work areas in which computers frequently need to be moved around and rearranged.

distribution group

One of two types of groups within Active Directory directory service in Microsoft Windows 2000, the other type being security groups.

Overview

While security groups can be listed in discretionary access control lists (DACLS) for controlling access to resources or sending e-mail to users, distribution groups can be used only for e-mail purposes. By sending e-mail to a distribution group, you send e-mail to every member of that group.

Distribution groups can be converted to security groups and vice versa as long as the domain is in native mode. You cannot perform conversion if the domain is in mixed mode.

See Also: group, security group

distribution list

A grouping of recipients in Microsoft Exchange Server that you can use to send a single message to multiple users simultaneously.

Overview

When a message is sent to a distribution list, it is sent to all recipients on the list. Distribution lists provide a convenient way of performing mass mailings to users. For example, a marketing department might create several hundred custom recipients for regular customers outside the Exchange organization. These custom recipients can then be included as members within a single distribution list. When the department wants to send e-mail to its customers announcing new products or services, the e-mail can be sent to the distribution list. A computer running Exchange Server (configured to expand distribution lists) makes sure that each custom recipient receives a copy of the message.

distribution server

A server that contains the source files for a software product and that is used to perform remote installations.

Overview

As an example, if you want to perform remote installations of Microsoft Windows 2000 Professional on client machines, you can copy the I386 folder from the CD onto a folder called NTWKS on your file server, and then

share this folder. Windows NT Workstation clients can then connect to this share and run the Setup program to upgrade their systems to Windows 2000 Professional.

Notes

When you copy files from the CD to a folder on the server, use the Xcopy command or, if you are using Windows Explorer, be sure to first choose Options from the View menu and select Show All Files. Otherwise, some hidden files will not be copied, and installation will fail.

DLC

Generally refers to the services that the data-link layer of the Open Systems Interconnection (OSI) reference model provides to adjacent layers of the OSI protocol stack. Specifically, a Data Link Control (DLC) is a specialized network protocol.

A client machine configured to send name resolution queries to a name server.

Overview

A Domain Name System (DNS) client is also called a resolver because it uses name servers to resolve a remote host's name into its Internet Protocol (IP) address. To accomplish this, it sends such a request to a name server (a DNS server), which then returns the IP address of the remote host.

DNS client software is built into operating systems that support TCP/IP to enable client machines to issue DNS queries to name servers. For example, on Microsoft Windows platforms, the DNS client software makes possible the use of DNS names for browsing the Internet using Microsoft Internet Explorer.

In Windows operating systems, you must configure the IP address of the DNS server in the client's TCP/IP property sheet in order for the DNS client software to work properly. With dial-up networking connections to the Internet, this information can be communicated to the client machine during negotiation of the Point-to-Point Protocol (PPP) connection with the Internet service provider (ISP).

DNS console

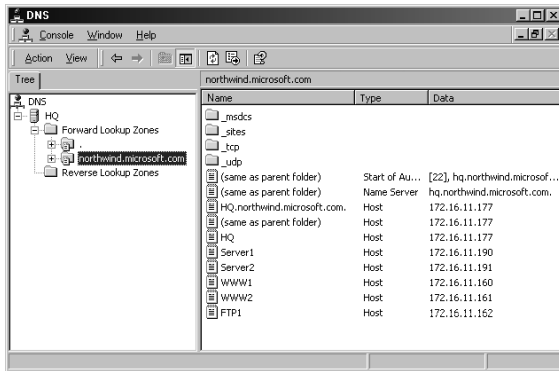

A snap-in for the Microsoft Management Console (MMC) in Microsoft Windows 2000 and Windows .NET Server that enables administrators to manage Windows 2000 Servers and Windows .NET Server running as Domain Name System (DNS) servers.

Overview

You can use the DNS console to

- Create and maintain the DNS database of host name to Internet Protocol (IP) address mappings
- Create and manage zones of authority
- Create start of authority (SOA), name server (NS), address (A), CNAME, and other resource records in the DNS database
- View DNS server statistics

- Control how zones are stored and replicated between DNS servers
- Configure how DNS servers will process DNS queries and handle dynamic updates
- Configure security for specific zones and resource records

DNS console. The DNS console in Windows 2000.

Notes

Windows 2000 Server and Windows .NET Server include a new command-line utility, `Dnscmd`, which can be used for managing certain aspects of DNS servers. This utility can be run from the command prompt or scripted into batch files to automate certain aspects of DNS administration. To use this command, you must install the Windows 2000 Support Tools from the `\Support\Tools` folder on the Windows 2000 product CD (Windows .NET Server also supports `Dnscmd` and is also part of the Windows .NET Server Support Tools). Type `dnscmd /?` to see the syntax for this command.

DNS database

The collection of database files, or zone files, and associated files that contain resource records for a domain.

Overview

Zone files are stored on a name server and are used to provide name resolution in response to name lookup requests. On Berkeley Internet Name Domain (BIND) name servers and Microsoft Windows NT Domain

Name System (DNS) servers, these DNS database files are stored as flat-file database (text) files, that is, simple ASCII files.

On a Windows NT server with the Microsoft DNS Service installed, DNS database files are located in the `\System32\DNS` directory. The DNS database files in this directory are

- The zone file, which has the extension `.dns` and contains the resource records that the DNS server manages
- The reverse lookup file, which resolves Internet Protocol (IP) addresses into host names
- The cache file, which has the names and IP addresses of the root name servers for DNS
- The boot file, which is used for startup configuration of the DNS server and is needed only for resolving the names of hosts that are located outside the zones for which the DNS server is authoritative

On a Windows 2000 or Windows .NET Server DNS server, DNS database information can be either stored in the preceding standard text files or can be integrated into Active Directory directory service, depending on how DNS is installed and configured on the machine. Using Active Directory for storing DNS database information has the benefits of Active Directory's enhanced security features and multimaster replication, providing faster and more efficient replication of DNS zone information than using standard DNS text files.

DNS namespace

The collection of domains, subdomains, and fully qualified domain names (FQDNs) within the Domain Name System (DNS).

Overview

DNS uses a namespace that is hierarchical in structure and is stored as a distributed database on servers called name servers. The term *namespace* can have two meanings:

- The abstract space of FQDNs that are used to identify hosts on the Internet or on a private corporate TCP/IP internetwork

- The physical space of DNS database files (zone files) that exist on name servers and that actually define or contain the abstract DNS namespace

D**Notes**

Active Directory directory service in Microsoft Windows 2000 and Windows .NET Server requires that a DNS namespace be configured in a domain-based implementation of Windows 2000 or Windows .NET Server in an enterprise.

DNS query

A request to a name server for name lookup.

Overview

DNS queries can occur two ways:

- Between resolvers and name servers
- Between name servers and other name servers

Queries can be answered by the queried name server from its local Domain Name System (DNS) database, from previously cached query results, or by a referral to another name server.

The three basic kinds of DNS queries are recursive queries, iterative queries, and inverse queries. For more information on these types of DNS queries, see their respective entries in this book.

DNSSEC

Stands for DNS Security Extensions, an enhancement of the Domain Name System (DNS) that supports cryptographic authentication of domain names.

See: DNS Security Extensions (DNSSEC)

DNS Security Extensions (DNSSEC)

An enhancement of the Domain Name System (DNS) that supports cryptographic authentication of domain names.

Overview

DNS Security Extensions (DNSSEC) uses public-key encryption and digital signatures to enable name servers to verify the identity of domain names. DNSSEC is a set of enhancements to existing name servers that will allow users to be certain that the Web site they are seeing in response to looking up a URL is in fact the one they desired and not some other “spoofed” site.

History

DNS has long been viewed in many quarters as the weak link in the Internet’s chain of protocols. DNS’s lack of security makes spoofing domain names easy, allowing malicious users to hijack Web traffic and redirect it to sites different from the ones users intended to access.

The most famous incident of Web site spoofing occurred in 1997. An IT (information technology) consultant in Washington State named Eugene Kashpureff set up servers to hijack Web traffic on the Internet and redirect it away from Network Solution’s InterNIC name servers to his own name servers, dubbed AlterNIC. As a result, a large segment of legitimate traffic on the Internet was disrupted for about a week, with significant financial loss to many involved.

Many other Web site spoofing incidents have occurred since then, highlighting the fundamental weakness with the security of DNS and driving forward the search for solutions that culminated in RFC 2535, which defines DNSSEC.

Implementation

DNSSEC works by enabling name servers to verify the information they exchange with each other using public key cryptography and digital signatures. Typically, a user enters a URL into his or her Web browser to access a site on the Internet. The browser’s Hypertext Transfer Protocol (HTTP) GET request is forwarded to the local name server, which is either a corporate name server in a large enterprise or a name server at a small to medium-sized company’s Internet service provider (ISP). This local name server then contacts a root name server to locate a name server authoritative for the top-level domain listed in the URL, which then directs the local name server to the name server authoritative for the second-level domain in the URL, and so on until the Internet Protocol (IP) address of the desired Web site can be looked up and communications

established. The role of DNSSEC in all this is that when these exchanges are going on between name servers, digital signatures are issued and verified at each stage to verify that the responses are being received from the actual name servers rather than spoofing name servers.

DNS Security Extensions (DNSSEC). *How DNSSEC works.*

DNSSEC works at both the zone and resource record levels to secure DNS information. DNSSEC requires several new resource records in name server databases:

- **SIG:** This resource record supplies digital signatures signed with private keys to encrypt resource record information.
- **PUB:** This resource record supplies the necessary public keys to decrypt encrypted resource record information.
- **NXT:** This resource record determines which records are mapped to which names.

Marketplace

The first DNS name server software to support DNSSEC is also the most popular in the Internet community, the Berkeley Internet Name Domain (BIND). DNSSEC is included in BIND 9, the latest release of the name server software, and is being packaged with most major UNIX operating systems including those from Sun Microsystems, Hewlett-Packard, and Red Hat Linux. The funding for developing DNSSEC for BIND 9 was provided by the U.S. Defense Information Systems Agency (DISA) and the work was done by NAI Labs and the Internet Software Consortium (ISC).

Although larger enterprises will likely move quickly to upgrade their name servers to support DNSSEC, smaller businesses may balk at the expense involved, particularly in the management of DNSSEC name servers. To meet this need, companies such as Nominum and UltraDNS Corporation are planning to offer outsourced DNSSEC services to such businesses.

Issues

A number of issues may delay the full-scale deployment of DNSSEC on name servers all across the Internet (DNSSEC must be widely deployed for it to work reliably):

- DNSSEC has greater processor and memory requirements than standard DNS in order to support the additional load of issuing and managing digital certificates and cryptographic keys.
- DNSSEC utilizes greater network bandwidth for its communications, both with DNS clients (resolvers) and with other name servers.
- DNSSEC is more complicated to install and maintain than standard DNS, particularly because of the key management issues involved.
- The root name servers of the Internet must be upgraded first for DNSSEC to properly operate, and this requires political decisiveness on the part of the Internet Corporation for Assigned Names and Numbers (ICANN), the agency that runs most of these servers.
- Regional and local ISPs must upgrade their name servers next in order for DNSSEC to succeed, and this involves additional costs due to hardware and management overhead that some ISPs may feel reluctant to commit.
- Finally, name servers have traditionally been managed on an “If it ain’t broke, don’t fix it” basis, where network administrators are reluctant to upgrade a server that is critical for the successful operation of a dot-com enterprise.

Despite all of these issues, there is still tremendous pressure for DNSSEC to go ahead, and it is likely to be fully deployed across the Internet in the next few years.

Prospects

DNSSEC is seen by many as an essential upgrade for the Internet's DNS infrastructure. Governments, B2B exchanges, financial servers, and others are likely to be early adopters of this technology. The U.S. military is already taking steps to implement DNSSEC by enhancing existing BIND 8 name servers with additional software to make the .mil top-level domain more secure.

DNS server

A server that is used to resolve host names or fully qualified domain names (FQDNs) into Internet Protocol (IP) addresses on a TCP/IP network.

Overview

A Domain Name System (DNS) server, which is also called a name server, accomplishes name resolution by accepting DNS queries from DNS clients (called resolvers) and by performing DNS queries among other DNS servers, depending on how the servers have been configured.

The most common type of name server in use on the Internet is the Berkeley Internet Name Domain (BIND) name server, which runs on the UNIX operating system. For Windows 2000 and Windows .NET Server deployments using Active Directory directory service, Microsoft Windows 2000 Server and Windows .NET Server can function as a DNS server and are managed using an administrative tool, DNS console, which is a snap-in for the Microsoft Management Console (MMC). Windows 2000 and Windows .NET Server DNS servers include advanced capabilities such as dynamic update, which allows DNS servers to update their DNS database files automatically using Dynamic Host Configuration Protocol (DHCP). Another feature of Windows 2000 and Windows .NET Server is tight integration of DNS and Active Directory. For example, when a Windows 2000, Windows XP, or Windows .NET Server client needs to locate a Windows 2000 or Windows .NET Server domain controller, the Net-Logon service uses the DNS server's support for the SRV resource record to allow registration of domain controllers in the local DNS namespace.

Notes

DNS servers can provide a simple means of load balancing connections to heavily used file or application servers such as Internet Information Services (IIS). The method is called Round Robin DNS, and it works as its name implies. Say you have three Web servers hosting identical content and you want to load balance incoming Hypertext Transfer Protocol (HTTP) requests across these servers. You can create three A records in the DNS zone file, each with the same host name but different IP addresses, one IP address for each Web server, as shown in this example:

www.northwind.microsoft.com	172.16.8.33
www.northwind.microsoft.com	172.16.8.34
www.northwind.microsoft.com	172.16.8.35

When a DNS client requests resolution of the name www.northwind.microsoft.com into its IP address, the DNS server returns all three IP addresses (.33, .34, .35), and the client chooses the first address (.33) and sends the HTTP request to the Web server associated with this address. The next time the DNS server receives the same name resolution request, it rotates the IP addresses in round-robin fashion (.34, .35, .33) and returns them to the client. The client picks the first address, which is now .34. This way, each DNS name resolution returns a different IP address, and the load is balanced between the Web servers.

The drawback to using Round Robin DNS is that if a server fails, DNS will continue to return the address of the failed server.

Document Object Model (DOM)

A set of programming interfaces for developing and managing Extensible Markup Language (XML) documents.

Overview

Document Object Model (DOM) has been a major driving force behind the development and proliferation of XML tools and standards. This is because DOM provides programmers with standard application programming interfaces (APIs) for representing and manipulating XML data. XML parsers based on DOM are widely implemented in Web browsers and other Web client tools, and the evolution of DOM is in large part driving the development of these tools.

DOM is a recommendation of the World Wide Web Consortium (W3C), and in its original version, it lets programmers model the data hierarchy of XML documents as objects that can be manipulated in Java, JavaScript, C++, and other languages. Using these and other languages, programmers can write scripts and applications that can dynamically modify the content, style, and structure of XML documents.

DOM was originally targeted toward small XML documents that could be loaded in entirety into memory and manipulated using repetitive operations. Because XML documents can be relatively large, a newer version called DOM 2 has been developed that includes a number of new features not supported by the original DOM, including support for

- Programmatically loading and saving XML documents
- Searching APIs for programmatic querying of properties and data in XML documents
- Programmatic implementation of custom namespaces for combining XML from different sources
- Programmatic management of cascading style sheets (CSS 1 and 2)

The W3C DOM Working Group is currently at work on DOM 3.

Marketplace

Support for DOM is included in products from many vendors of XML products, including Microsoft Corporation, Oracle Corporation, IBM, SoftQuad, and others. Microsoft Internet Explorer 5.5 also supports key aspects of DOM 2, including APIs for custom namespaces and cascading style sheets.

document type definition (DTD)

A file that defines the allowed structure of an Extensible Markup Language (XML) document.

Overview

Document type definitions (DTDs) are used in XML to specify the structure of documents. For example, Hypertext Markup Language (HTML) documents are defined by the HTML DTD, which is implemented in Web browsers such as Microsoft Internet Explorer and Web page editing software such as Microsoft FrontPage. The DTD specifies which kinds of tags are mandatory and which are optional, and also the range of allowed values for each type of tag.

DTD originated as part of the Standard Generalized Markups Language (SGML) specification developed by the International Standards Organization (ISO) in the 1980s. DTD is now a basic part of the XML specification.

Implementation

DTDs are implemented as plain-text files. They use a highly condensed language or syntax, which is very concise and can be parsed rapidly and efficiently. Schemas are another feature of XML and provide functionality similar to DTDs. The main difference is that schemas are more verbose than DTDs since they are written in XML instead of the more concise (but less readable) DTD language.

DoD model

A networking model developed by the U.S. Department of Defense (DoD).

Overview

The DoD model was developed in the 1970s as the networking model for the Transmission Control Protocol/Internet Protocol (TCP/IP), which was first deployed by in the ARPANET project and is now the worldwide de facto standard for the Internet. The DoD model is older than the seven-layer Open Systems Interconnection (OSI) model, which was developed in the 1980s by the International Organization for Standardization (ISO) to provide a more detailed framework for developing network protocols.

Architecture

The DoD model consists of four layers. These layers map loosely to the seven-layer OSI model in the fashion described below. Describing the DoD layers from the top down, they are

- **Application/Process Layer:** Also called simply Application Layer, this layer covers the functions of the top three layers of the OSI model. TCP/IP protocols at this layer include Hypertext Transfer Protocol (HTTP), File Transfer Protocol (FTP), Simple Mail Transfer Protocol (SMTP), Simple Network Management Protocol (SNMP), and many others.
- **Host-to-Host Layer:** Also called the Transport Layer, this layer functions similarly to the OSI model Transport layer. Protocols at this layer include Transmission Control Protocol (TCP) and User Datagram Protocol (UDP).
- **Internetworking Layer:** This layer functions similarly to the OSI model Network Layer. Protocols at this layer include Internet Protocol (IP), Internet Control Message Protocol (ICMP), Internet Group Membership Protocol (IGMP), and Address Resolution Protocol (ARP).
- **Network Interface Layer:** This layer functions similarly to the OSI model Data Link and Physical layers. There are no TCP/IP protocols at this layer. Instead, TCP/IP runs over standard networking architectures such as Ethernet and Token Ring, which are defined at this layer.

Domain Admins

A built-in group on Microsoft Windows NT, Windows 2000, and Windows .NET Server networks for users who need administrator-level access to systems.

Overview

The Domain Admins group simplifies administration of users on the network. It is a global group and does not have any preassigned system rights. The initial membership of the group is the sole user account called Administrator. Other user accounts that are added to this group gain rights and privileges equivalent to those of the Administrator account and can perform actions similar to those of the Administrator account. All network administrators in a given domain should be members of this group.

Notes

On Windows 2000– and Windows .NET Server–based networks, the Domain Admins group is created by default in the Users organizational unit (OU) within Active Directory directory service.

domain blocking

The ability to block traffic from a specific Domain Name System (DNS) domain.

Overview

Domain blocking is a security technology used in Microsoft Internet Information Server (IIS) Web servers to protect them from undesirable traffic. It was first introduced with IIS4.

Domain blocking allows IIS administrators to grant or deny access to content on the server based on a client's Internet Protocol (IP) address, subnet, or Internet domain name. This is a useful security feature for protecting machines running Internet Information Server

from repeated attack by hackers. Domain blocking can be applied at various levels, including the following:

- All virtual servers on the machine (master level)
- A specific virtual server
- A specific virtual directory
- A specific file

domain controller

A server running Microsoft Windows NT, Windows 2000, or Windows .NET Server that manages security for the domain.

Overview

Users and computers that need to obtain access to network resources within the domain must be authenticated by a domain controller in the domain. Windows NT domain controllers are the foundation of Windows NT Directory Services (NTDS), and Windows 2000 and Windows .NET Server domain controllers are based on Active Directory directory service.

In a Windows NT–based network, the domain controllers form a hierarchy. There are two types of Windows NT domain controller:

- **Primary domain controller (PDC):** This contains a writeable master copy of the domain directory database. A domain can have only one PDC, which is at the top of the domain controller hierarchy. All changes to directory information (such as user accounts or passwords) must be made on the PDC.
- **Backup domain controller (BDC):** This contains read-only replicas of the domain directory database stored on the PDC. There can be zero or more BDCs per domain. BDCs provide redundancy and load balancing for the domain. Periodically, the BDCs in a domain undergo directory synchronization with the PDC to ensure that the BDCs contain an accurate copy of the domain directory database. This replication ensures the proper functioning of the NTDS.

A Windows 2000 or Windows .NET Server domain controller is any Windows 2000 server or Windows .NET Server with the optional Active Directory installed.

Windows 2000 and Windows .NET Server domain controllers contain a complete, writeable copy of the Active Directory information for the domain in which they are installed. Run the Active Directory Installation Wizard to promote any Windows 2000 or Windows .NET Server member server to the role of a domain controller. A domain controller manages information in the Active Directory database and enables users to log on to the domain, be authenticated for accessing resources in the domain, and search the directory for information about users and network resources. A Windows 2000 or Windows .NET Server domain controller contains a writeable copy of the domain directory database.

Unlike in a Windows NT–based network, where domain controllers are in a hierarchy, all domain controllers in a Windows 2000– or Windows .NET Server–based network are equal, and changes to the domain directory database can be made at any domain controller. Replication of directory information between Windows 2000 and Windows .NET Server domain controllers follows a multi-master model. In this configuration, each domain controller acts as a peer to all other domain controllers. In other words, there are no primary or backup domain controllers in Windows 2000 or Windows .NET Server, only domain controllers.

Although most domain controller options (sending and receiving updates that add, move, copy, and delete objects from the directory) are multimaster in nature, a few domain controller operations function on only certain domain controllers. These special functions are called flexible single-master operations (FSMO) and perform functions such as modifying the schema, assigning pools of relative identifiers to other domain controllers within a domain, emulating a Windows NT PDC for downlevel compatibility with Windows NT domain controllers, updating security identifiers and distinguished names in cross-domain objects when such an object is moved or deleted, and ensuring that all domain names within a forest are unique.

Uses

An important issue regarding domain controllers in Windows 2000– and Windows .NET Server–based networks is where to place them. After an administrator implements Active Directory and populates its initial information, most Active Directory–related traffic will

D

come from users querying for network resources. The key to optimizing user queries is in how you locate the domain controllers and the global catalog servers on your network. Placing a domain controller at each physical site optimizes query traffic but increases replication traffic between sites. Nevertheless, the best configuration is usually to place at least one domain controller at each site with a significant number of users and computers.

In a pure Windows 2000 networking environment, all domain controllers can be configured to run in native mode. If you have a mix of Windows NT 4 and Windows 2000 domain controllers, the Windows 2000 domain controllers must be configured to run in mixed mode.

Notes

To upgrade a Windows NT–based network to Windows 2000, upgrade the PDC first. This allows the domain to immediately join a domain tree, and administrators can administer the domain using the administrative tools of Windows 2000 and create and configure objects in Active Directory.

If you need to move a Windows NT domain controller to a new domain, you must reinstall Windows NT. Domain controllers cannot migrate from one domain to another because when you create a domain, a unique security identifier (SID) is created to identify the domain, and domain controllers have this SID hard-coded into their domain directory database.

You can use the administrative tool Active Directory Users and Computers to convert a Windows 2000 domain controller from mixed mode to native mode. However, domain controllers running in native mode cannot be changed to mixed mode. If you create a new domain controller for an existing Windows 2000 domain, this new domain controller is referred to as a replica domain controller. Replica domain controllers are typically created to provide fault tolerance and better support for users who access resources over the network.

domain (DNS)

A collection of related hosts in the hierarchical Domain Name System (DNS).

Overview

Domains are the building blocks of DNS. A domain consists of a group of nodes in the DNS namespace that have the same domain name. Domains are organized hierarchically in the DNS namespace, with the topmost domain called the root domain.

DNS domains can be classified as one of the following:

- A parent domain, which contains other domains. An example of a parent domain is microsoft.com.
- A child domain, or subdomain, which is contained within a parent domain. Examples of child domains in the microsoft.com parent domain are northwind.microsoft.com and marketing.microsoft.com.

Domain names can include only the characters a–z, A–Z, and 0–9, the dash (-), and the period. A name that completely identifies a host in the DNS namespace is called a fully qualified domain name (FQDN).

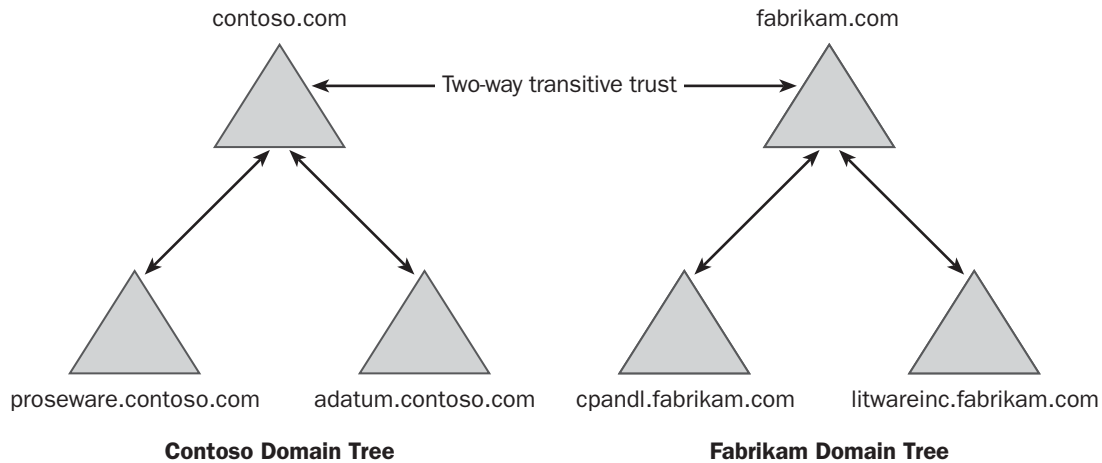

See Also: *Domain Name System (DNS)*

domain forest

Also called simply a forest, a logical structure formed by combining two or more Microsoft Windows 2000 or Windows .NET Server domain trees.

Overview

Forests provide a way of administering enterprise networks for a company whose subsidiaries each manage their own network users and resources. For example, a company called Contoso, Ltd. might have a domain tree with the root domain contoso.com, and a subsidiary company called Fabrikam, Inc. might have a domain tree with the root domain fabrikam.com. Note that these two companies do not share a contiguous portion of the DNS namespace; this is typical of trees in a forest. The two companies might want to administer their own users and resources but make those resources available to each other's users. They can combine the two domain trees into a forest by establishing a two-way transitive trust between the root domains of the two trees.

Domain forest. Example of a domain forest.

All trees in a forest must share a common directory schema and global catalog. The global catalog holds information about all objects in all domains of the forest and acts as an index of all users and resources for all domains in the forest. By searching the global catalog, a user in one domain can locate resources anywhere in the forest. The global catalog contains only a subset of the attributes of each object. This ensures fast searches for users trying to locate network resources.

Domain Guests

A built-in group on Microsoft Windows 2000 and Windows .NET Server networks.

Overview

The Domain Guests group simplifies administration of users on the network. It is a global group and does not have any pre-assigned system rights. The initial membership of the Domain Guests group is the sole user account called Guest. Other user accounts that are added to this group gain the rights and privileges equivalent to those of the Guest account and can perform actions similar to those of the Guest account. Domain Guests are typically users who are given occasional, temporary access to network resources.

Notes

The Domain Guests group is created by default in the Users organizational unit (OU) within Active Directory directory service. Normally, the only member of this group is the Guest account, but when Internet Information Services (IIS) is installed, additional guest accounts are created for use by IIS.

domain local group

A type of group in a Microsoft Windows 2000– or Windows .NET Server–based network.

Overview

Windows 2000 and Windows .NET Server use groups to organize users or computer objects for administrative purposes. Groups can have different scopes, or levels of functionality. The scope of a group can be a single domain, a group of domains connected by trust relationships, or the entire network.

Domain local groups are Windows 2000 and Windows .NET Server groups whose scope is restricted to the specific domain in which they are defined. Domain local groups are used to provide users with access to network resources and to assign permissions to control access to these resources. Domain local groups have open membership, which means that you can add members from any domain to them.

D

To use a domain local group, you first determine which users have similar job responsibilities in your enterprise. Then you identify a common set of network resources in a domain that these users might need to access. Next, you create a domain local group for the users and assign the group appropriate permissions to the network resources. This procedure is called A-G-DL-P (access, group, domain local, permissions), which is a variation of the AGLP administration paradigm used in Windows NT-based networks.

Notes

If network resources within a domain are used only within the domain, you can group users in the domain using domain local groups. If your scope of resource usage is several domains linked by trust relationships, use global groups instead. If your network is a pure Windows 2000– or Windows .NET Server–based network and your domain controllers are running in native mode, you can use universal groups as well.

domain master browser

A role of a browser computer on a Microsoft Windows–based network.

Overview

Domain master browser is one of the browser roles for the computer browser service on Windows networks. A domain master browser must be a machine running Windows NT, Windows 2000, or Windows .NET Server.

The role of the domain master browser is to collect the master list of available network resources in the domain. The domain master browser then distributes this list to master browsers on each subnet. If the domain has only one subnet, the domain master browser is also the master browser for that subnet.

Notes

A Windows NT domain has only one domain master browser, which is always the primary domain controller (PDC).

domain (Microsoft Windows)

A model developed by Microsoft Corporation for grouping computers together for administrative and security purposes.

Overview

Computers on a Microsoft Windows NT, Windows 2000, or Windows .NET Server network that are in the same domain share a common directory database of security information such as user accounts, passwords, and password policies. Domains can span geographical boundaries and networks; an enterprise can have branches in several continents with all machines belonging to a single domain. Alternatively, a single network or location can have multiple domains installed, with or without trust relationships between them.

Domain-based networks have the following features:

- **Centralized administration:** The entire network can be administered from a single location.
- **Single-user logon:** Users need only one user account to access any workstation on the network.
- **Universal resource access:** Users can access any network resource for which they have the appropriate permissions.

Implementation

Domains can contain different types of computers, that is, computers performing various different roles. Typically, the following kinds of computers are members of the domain:

- **Domain controllers:** These computers maintain the database of directory information for the domain. In Windows NT, this database is called the Security Accounts Manager (SAM) database, while in Windows 2000 and Windows .NET Server, this information is stored in Active Directory directory service. Domain controllers periodically exchange directory information using directory replication so that the information in any given domain controller is kept up to date. (If the information stored in a domain controller is out of date, users might have trouble logging on with that particular domain controller or finding recently shared resources on the network.)

- **Member servers:** These are stand-alone servers typically used for file and print services, Web services, or running applications such as Microsoft SQL Server. Member servers cannot authenticate users as domain controllers can.
- **Workstations or client computers:** These participate in the security policies of the domain and are members of the domain, but they are used as desktop machines for users instead of as network servers.

A Windows NT or Windows 2000 network can be installed as either a domain or a workgroup. The domain model is preferable because it allows computers to share a common security policy and a common domain directory database. Machines running Windows Millennium Edition (Me), Windows 98, Windows 95, and legacy 16-bit Windows machines can also participate in domain security on Windows NT and Windows 2000 networks but are not considered full members of the domain because they have no computer accounts within the domain directory database.

A Windows NT domain requires only one primary domain controller (PDC) and can have a number of backup domain controllers (BDCs). By creating a PDC, you create a new domain. Windows NT member servers and workstations can join a domain. Other systems, such as computers running Windows 95 and Windows 98, can participate in a domain but are not considered members of the domain because they have no computer accounts in the domain directory database.

Domain (Microsoft Windows). This illustration shows a Windows 2000 domain.

Windows 2000 domains use peer domain controllers, which are all equal in status. In Windows 2000, domains are core entities within Active Directory and act as a boundary for network security and for the replication of directory information over the network. If you establish a security policy in one domain, the settings, rights, and discretionary access control lists (DACLS) of that policy are limited to that domain. Domains are also the fundamental containers for all network objects within them. Domains contain users, groups, computers, and other directory objects. These objects can be grouped together using a hierarchy of organizational units (OUs).

domain model

A model for building an enterprise-level network using Microsoft Windows NT or Windows 2000 domains.

Overview

Windows NT uses domain models for building enterprise networks radically different from those used by Windows 2000 and Windows .NET Server. In Windows NT networks, four main domain models can be implemented:

- **Single domain model:** This model keeps all of the machines in the network in a single domain and is usually implemented in smaller companies
- **Single master domain model:** This model separates resource domains from a master or accounts domain and is suitable for companies with a hierarchical organizational structure
- **Multiple master domain model:** This model uses multiple accounts or master domains and is suitable for large organizations that span different countries, regions, or continents
- **Complete trust model:** This model is used by very decentralized organizations or during the transition period when two companies merge

Because of their two-way transitive trusts between domains, Windows 2000 and Windows .NET Server are capable of building more flexible domain structures than Windows NT. In addition to the single domain model above, Windows 2000 and Windows .NET Server

domains can be linked together hierarchically in domain trees, and domain trees can be joined at their roots to form domain forests.

D

Windows NT, Windows 2000, and Windows .NET Server can be scaled for implementation in enterprise-level businesses that support thousands of users and cover geographically diverse regions, with Windows 2000 and Windows .NET Server being the more scalable platforms. Choosing the correct domain model for implementing your network can greatly simplify administration of your network.

domain modes

A mode of operation for domain controllers in Microsoft Windows 2000– and Windows .NET Server–based networks.

Overview

Windows 2000 and Windows .NET Server domain controllers are computers that contain a writeable copy of Active Directory directory service. You can convert a Windows 2000– or Windows .NET Server–based server to a domain controller by running the Active Directory Installation Wizard on that machine. You can run Windows 2000 or Windows .NET Server domain controllers in either of two modes (though .NET Server introduces a new mode called “Windows .NET version 2002,” which is exclusively for .NET Server–based networks):

- **Mixed mode:** This mode provides backward compatibility with Windows NT domain controllers (downlevel domain controllers). This mode supports networks with a mixture of Windows 2000, Windows .NET Server and Windows NT domain controllers and allows them to interoperate. Multi-master replication cannot be used in mixed-mode environments.
- **Native mode:** This mode interoperates only with other Windows 2000 or Windows .NET Server domain controllers. Native mode should be used when there are no longer any downlevel domain controllers on the network.

Notes

By default, Active Directory is installed on a Windows 2000 server or Windows .NET Server in mixed mode. You can change a domain controller from mixed mode to native mode, but not vice versa. Use the administrative tool Active Directory Users and Computers to perform the change.

domain name

A name for a domain within the Domain Name System (DNS).

Overview

Domain names are used by companies and organizations to provide a uniform naming scheme for hosts on their Transmission Control Protocol/Internet Protocol (TCP/IP) internetworks and for providing friendly names for Web servers, mail servers, and other servers that are exposed to the Internet.

Domain names must be registered with a domain name registry before they can be used. Formerly this meant registering with the Internet Network Information Center (InterNIC), and later on Network Solutions. Today a number of different domain name registrars exist, each of which must be accredited by the Internet Corporation for Assigned Names and Numbers (ICANN) in order to operate. ICANN is the ultimate controlling organization for domain names and determines both generic and country-specific top-level domains (TLDs).

Uses

Owning a domain name is essential in today’s business world as the dot-com enterprise becomes the standard model for business. A company’s domain name typically reflects the company’s trademark name or logo—for example, the microsoft.com domain owned by Microsoft Corporation. Because company names can be registered at the state or federal level, companies in different states or countries might want to register identical domain names. Unfortunately, the DNS was not established with consideration of these trademark issues, and the courtroom has become a common arena for resolving domain name ownership disputes.

The most popular domain names that companies register are the .com domain names. These were originally intended for commercial enterprises only, but they are also used by individuals, nonprofit organizations, and other entities that want to establish a clear presence on the Internet. About 75 percent of all registered domain names belong to the .com top-level domain. As of 2000, there were about 15 million registered domain names worldwide, and this figure is climbing rapidly.

Prospects

The Internet and its Domain Name System were developed in the United States, and the fact that the Internet is now a worldwide entity has put new pressures on DNS. Countries and regions have pressed for modifications to DNS to allow domain names to be registered in languages other than English, including languages that do not use Roman alphabet characters, such as Chinese. The IETF has established an Internationalized Domain Name (IDN) working group to develop such a system, which is likely to be based on the Unicode standard for internationalization of alphabets. The goal is to implement non-English DNS with minimal modifications to existing DNS itself.

ICANN is also in the process of creating additional top-level domains as alternatives for companies that are unable to register suitable .com domain names and for other purposes such as personal home pages. For the latest developments in this regard, see the ICANN Web site at www.icann.org.

Notes

In an interesting development, a commercial company called New.net has created its own new set of TLDs and is selling domain names based on them without the ICANN's approval. This is probably an attempt to apply market pressure to what is often perceived as ICANN's slow, politically based decision-making process of creating new TLDs. New.net is collaborating with commercial DNS provider UltraDNS to provide support for these new TLDs on name servers. To do this, Internet service providers (ISPs) install special software on their own name servers that allows client lookups for these new TLDs to be forwarded directly to UltraDNS's name servers. Users whose ISPs do have such software installed on their name servers can download a free plug-in from New.net to allow them to access sites using these TLDs.

Domain Name System (DNS)

A hierarchical naming system for identifying Transmission Control Protocol/Internet Protocol (TCP/IP) hosts on the Internet.

Overview

The Domain Name System (DNS) is a distributed, hierarchical system that provides

- A method for identifying hosts on the Internet using alphanumeric “friendly” names called fully qualified domain names (FQDNs) instead of using difficult to remember numeric Internet Protocol (IP) addresses
- A distributed mechanism for storing and maintaining a database of the FQDNs and their associated IP addresses for all hosts on the Internet
- A method for locating hosts on the Internet by resolving their FQDN into their associated IP address so that network communication can be initiated with the host

History

Until 1983 the Internet computers used locally stored Hosts files to perform name resolution. Hosts files are text files that are basically lists of FQDNs and their associated IP addresses for remote hosts that the local host may need to communicate with. With the rapid growth of the Internet, however, updating these Hosts files became an unmanageable chore—each machine had to have its own local Hosts file that needed to be kept up to date, and whenever a host was added to the Internet or removed from it, the Hosts file needed an appropriate modification.

To solve this problem, the hierarchical DNS naming system was invented in 1984 and name servers were deployed across the Internet. The original RFCs 882 and 883 that defined DNS have since been replaced by RFCs 1034 and 1035, and additional RFCs have been added for additional features added to DNS.

Today DNS functions like a backbone for the Internet—without DNS, network communications over the Internet would not be possible.

D

Uses

Although the primary use of DNS is as the naming system for the Internet, large private TCP/IP internetworks sometimes used DNS internally with their own private name servers. This practice is rare now, however, as most private networks are now connected to the Internet.

DNS is essential to the operation of Active Directory directory service in Windows 2000 and Windows .NET Server. Active Directory uses the DNS as its naming system for Windows 2000 and Windows .NET Server hosts, and DNS servers provide name resolution services to enable network communications to take place on a Windows 2000– or Windows .NET Server–based network.

Not all name servers support the necessary DNS features that Active Directory requires. In order to implement Active Directory, name servers must support SRV records described in RFC 2052bis (SRV records enable Windows 2000 and Windows .NET Server clients, including Windows XP, to locate a domain controller for network authentication purposes). In addition, the following advanced DNS features are recommended for name servers that will support Active Directory:

- DNS dynamic updates described in RFC 2136.
- DNS change notification described in RFC 1996.
- Incremental zone transfer (IXFR) described in RFC 1995.

Windows 2000 and Windows .NET Server DNS service supports all of the above features by default. If you want to use Berkeley Internet Name Domain (BIND) name servers to support an Active Directory implementation, you must use at least BIND 8.1.2 and preferably BIND 8.2 or higher. Make sure you also disable name checking so your BIND name servers will ignore the illegal underscore character used by Active Directory's version of DNS.

Note that in BIND, name servers zone information is stored in text files. In Windows 2000 and Windows .NET Server, zone information can be stored either in text files or stored in and replicated using Active Directory.

Implementation

For DNS to work, four elements are required:

- A naming system that uniquely assigns each host on the Internet a DNS name.
- Name servers that keep track of the DNS namespace (collection of DNS names).
- Resolvers that can query the name servers asking what IP address corresponds to a particular DNS name.
- A way of assigning domain names to companies and organizations that have networks that need to be connected to the Internet.

Domain Name System (DNS). The hierarchical structure of DNS.

The DNS naming system assigns a unique name to each TCP/IP host on the Internet. Here the word host typically refers to servers, workstations, routers, TCP/IP printers, and similar devices. This unique name for a host is called the fully qualified domain name (FQDN) of the host.

The DNS namespace is defined as the collection of all FQDNs for all hosts on the Internet. This DNS namespace is hierarchical in structure, beginning with the root domain, which branches to top-level domains, then second-level domains, and so on to the individual host name. The FQDN barney.northwind.microsoft.com can be broken down as follows:

- **Host name:** barney
- **Third-level domain:** northwind (stands for Northwind Traders Ltd., a fictitious Microsoft subsidiary)
- **Second-level domain:** microsoft (Microsoft Corporation)
- **Top-level domain:** com (commercial domain)

The root domain has a null label and is not expressed in the FQDN.

The DNS namespace is stored as a distributed database on name servers located at various points on the Internet. Each name server on the Internet is responsible for a subset of the DNS namespace known as a zone. Each zone can consist of one or more domains and subdomains over which the zone is said to be authoritative.

The most important name servers on the Internet are the dozen or so root name servers, which are responsible for maintaining the infrastructure of the domain name system. These root name servers are maintained mostly by the Internet Network Information Center (InterNIC) and by U.S. military agencies (because the Internet evolved from the ARPANET project of the U.S. Defense Department in the 1970s).

Name servers typically store their DNS information in text files called zone files, which consist of a series of resource records (but Microsoft Windows 2000 and Windows .NET Server can do this differently, as discussed later in this article). There are many types of resource records, but the most common type is the A (address) record, which maps the host name or FQDN of a single host to its IP address.

The main function of a name server is to answer queries from DNS clients called resolvers. A resolver contacts a name server, asking it for the IP address associated with a given host name or FQDN. The name server then replies to the resolver with the IP address of the host or contacts a different name server for this information if it is unable to provide it itself.

All name servers can answer queries from resolvers or forward these queries to other name servers. However, name servers also function in four specific roles within the Domain Name System:

- **Primary name server:** This type of name server stores the master copy of the zone file for the zones that the name server has authority over
- **Secondary name server:** This type obtains its zone files by means of a zone transfer from a master name server
- **Master name server:** This type of name server is capable of providing zone information to secondary name servers

- **Caching-only name server:** This type contains no zone information of its own but can cache names resolved by other name servers and then use this cached information to respond to subsequent name lookups

Finally, companies and organizations can obtain domain names for their networks from domain name registrars. These registrars are accredited by the Internet Corporation for Assigned Names and Numbers (ICANN), which used to maintain the DNS system itself until recently.

Marketplace

Most ISPs run their own name servers (usually BIND) and implement registered DNS domains for a small fee to allow companies to run Web servers and mail servers accessible to the Internet. A new type of player is the pure-play DNS service provider, which runs its own dedicated DNS name servers and provides managed, high-availability DNS services to companies for a monthly service charge. Once such company is UltraDNS, which uses a network of redundant DNS servers for failover support and locates these servers near the Internet's backbone for best performance.

Issues

Security is the most important issue regarding DNS. Since DNS was designed to be completely open (any host on the Internet may query any name server), it is inherently insecure and open to attack. The most important type of attack is the denial of service (DoS) attack, which floods a name server with so many false DNS queries that it is unable to respond to real queries. Access to a company's Web server can be completely stopped through DoS attacks on name servers.

Since DNS is critical to the operation of the Internet, it is also viewed sometimes as a prize target by hackers seeking to disrupt the Internet's operation (actually these are more like anarchists than hackers, since a true hacker needs DNS in order to intrude into networks connected to the Internet). BIND name servers, which are the primary form of name server used on the Internet, have had a number of well-publicized vulnerabilities discovered in recent years, and an essential task of Internet service providers (ISPs) is keeping up with patches for their BIND name servers to protect them against attack.

Prospects

DNS will continue to play an essential role for the Internet, but with the transition to the new IPv6 addressing scheme, DNS needs a few modifications. The most important modifications are the inclusion of two new resource record types:

- **A6 record:** This is the counterpart for the A (address) record for IPv4 and maps a host name or FQDN to its IPv6 address to support name lookups.
- **DNAME:** This is the IPv6 counterpart of the CNAME record in IPv4.

In addition, reverse name resolution using PTR (pointer) records is different in IPv6 DNS. Specifically, while IPv4 DNS uses the in-addr.arpa domain for such reverse name resolution, IPv6 DNS uses a new domain called IP6.INT.

Finally, during the transition between IPv4 to IPv6 both versions of DNS will need to be supported (probably for many years), and to make this possible, the AAAA record was created to enable IPv4 name servers to provide IPv6 addresses to resolvers performing name lookups.

AAAA records are supported by BIND 8.1 and higher, while IPv6 DNS is supported by BIND 9.

Notes

On smaller TCP/IP networks, Hosts files can be used instead of DNS to support name lookups, while on legacy Windows NT-based networks, Windows Internet Name Service (WINS) provided NetBIOS name resolution as an alternative to DNS. WINS is also supported by Windows 2000 and Windows .NET Server but only for downlevel compatibility with Windows NT in networks that have not been fully upgraded from Windows NT to Windows 2000 or Windows .NET Server.

Windows 2000 and Windows .NET Server also use other naming conventions besides DNS. For example, to locate objects within Active Directory, the following naming conventions can be used:

- The Lightweight Directory Access Protocol (LDAP) naming convention of distinguished names and relative distinguished names (RDNs). This includes LDAP Uniform Resource Locators (URLs).

- User principal names for identifying users and groups.
- Security Accounts Manager (SAM) account names for user accounts.
- Universal Naming Convention (UNC) paths for shared network resources.

domain tree

A hierarchical grouping of Microsoft Windows 2000 or Windows .NET Server domains.

Overview

Domain trees are created by adding one or more child domains to an existing parent domain. Domain trees are used to make a domain's network resources globally available to users in other domains.

Domain tree. Example of a domain tree.

In a domain tree, all domains share their resources and security information to act as a single administrative unit. A user who logs on anywhere in a domain tree can access file, printer, and other shared resources anywhere in the tree if he or she has appropriate permissions. A domain tree has only one Active Directory, but each domain controller in a tree maintains only the portion of Active Directory directory service that represents the objects in that particular domain.

Domains in a domain tree are joined using two-way transitive trusts. These trusts enable each domain in the tree to trust the authority of every other domain in the tree for user authentication. This means that when a domain joins a domain tree, it automatically trusts every domain in the tree.

For child domains to be part of a domain tree, they must share a contiguous namespace with the parent domain. The namespace of a Windows 2000 or Windows .NET Server domain is based on the Domain Name System (DNS) naming scheme. For example, in the illustration, the child domains `proseware.contoso.com` and `adatum.contoso.com` share the same namespace as the parent domain `contoso.com`. In this example, `contoso.com` is also the name of the root domain—the highest-level parent domain in the tree. The root domain must be created first in a tree.

All domains in a domain tree have their directory information combined into a single directory: Active Directory. Each domain provides a portion of its directory information to an index on the domain controllers. By searching this index, users can locate and access shared resources, applications, and even users anywhere in the domain tree.

Notes

Two or more domain trees that do not share a contiguous namespace can be combined into a domain forest.

domain user account

One of two types of user accounts available on a Microsoft Windows 2000– or Windows .NET Server–based network.

Overview

User accounts enable users to log on to domains or computers and access any resources in the domain for which they have appropriate permissions. This is in contrast to local user accounts, which are used only for logging on to a specific machine (such as a member server) and accessing resources on that machine.

Domain user accounts are created in Active Directory directory service and stored in organizational units

(OUs). Domain user account information is replicated to all domain controllers in a domain using directory replication. This replication enables the user to quickly and easily log on from any part of the domain.

You create domain user accounts using the administrative tool called Active Directory Users and Computers, a snap-in for the Microsoft Management Console (MMC). You can create domain user accounts in the default Users OU or in any other OU that you have created in Active Directory.

Notes

Windows 2000 and Windows .NET Server also include a number of built-in accounts that simplify the task of administering users on a network. The two built-in user accounts are the Administrator and Guest accounts.

Domain Users

A built-in group on Microsoft Windows NT, Windows 2000, and Windows .NET Server networks.

Overview

The Domain Users group simplifies administration of users on the network. It is a global group and does not have any preassigned system rights. Its initial membership is empty until ordinary network users are created for the domain. User accounts that are added to this group gain the rights and privileges that are assigned to ordinary users in the network, such as the right to log on over the network. All ordinary users on the network should be members of this group.

Notes

On Windows 2000– and Windows .NET Server–based networks, the Domain Users group is created by default in the Users organizational unit (OU) within Active Directory.

DoS

Stands for Denial of Service, any attack conducted against a system that tries to prevent legitimate users from accessing the system.

See: *denial of service (DoS)*

DOS

Stands for Disk Operating System, which is short for Microsoft Disk Operating System (MS-DOS), the venerable operating system created by Microsoft Corporation for the first IBM personal computer in 1981.

See: MS-DOS

down

The state of a network when some or all network communications are disrupted.

Overview

Common reasons for networks being down include

- Loose connectors on cables
- Breaks or shorts in cables
- Failed networking components

Indications that the network might be down include

- Users complain that they cannot log on to the network or access certain network resources.
- Alarm systems in Simple Network Management Protocol (SNMP) management software start sending administrative alerts or e-mail to administrators.
- The uninterruptible power supply (UPS) unit in the wiring closet generates its annoying high-pitched tone.

drain wire

An uninsulated wire included in shielded cabling that runs the length of some coaxial cabling or shielded twisted-pair (STP) cabling.

Overview

The drain wire makes contact with the foil sleeve or mesh along the wire. The externally exposed portion of the drain wire should be connected to a secure ground connection. This ensures that the wire is properly grounded and that the shielding in the wire operates effectively. It also helps to maintain the two ends of the wire at the same voltage with respect to ground. If voltage differences form between the ends of a network

cable, they can lead to a sudden voltage surge or discharge that can damage attached networking devices.

See Also: coaxial cabling, shielded twisted-pair (STP) cabling

drop

Another name for a wall plate or some other receptacle for connecting workstations to a local area network (LAN).

Overview

For example, a network administrator might say, “This room has 24 drops, and 6 are still available.” This means that there are 24 wall plate connections on the walls of the room, and 18 of them have drop cables attached to them to connect them to computers in the room. The other end of the drops usually terminates at a patch panel in the wiring closet. Another name for a drop is a *LAN drop*.

See Also: premise cabling, wall plate

drop cable

In Standard Ethernet networks, a cable connecting a computer’s network interface card (NIC) to a transceiver attached to a thicknet cable.

Overview

In Standard Ethernet networks, a drop cable is also called a transceiver cable. More generally, a drop cable is any short cable connecting a computer’s NIC to a wall plate. Drop cables allow computers to be easily disconnected and reconnected from the network so that you can move them around in the room. Drop cables are generally needed because horizontal cabling connecting patch panels in wiring closets terminates at wall plates in the work areas, but computers in the work areas are distributed throughout the entire room. In a more permanent networking configuration, wall plates might be located on floors and very short drop cables might be used to connect the computers to the network.

Dr. Watson

A Microsoft Windows utility that intercepts software faults and provides the user with information on which software faulted and why the fault occurred.

Overview

In earlier versions of Windows, this information was terse and cryptic, but it was greatly expanded and reorganized in the version of Dr. Watson included with Windows 98, as shown in the screen capture. However, this information is usually not helpful to the person running the software. Dr. Watson is primarily of interest to the providers of the software to determine what caused the software to crash. A piece of software that frequently generates Dr. Watson messages can be considered buggy, and you should contact your software vendor for a fix or a replacement.

Dr. Watson. A report generated by Dr. Watson.

DS

Stands for Differentiated Services, a system for service classification of network traffic.

See: *Differentiated Services (DS)*

DS-0

Also known as DS0, stands for Digital Signal Zero, a transmission standard for digital telecommunications.

Overview

DS-0 defines a transmission rate of 64 Kbps and can carry either a single voice channel or data. Telecommunication carriers transmit digital signals in multiples of

DS-0 called DS-1, DS-2, and so on. These multiples differ depending on whether you are dealing with the T-carrier system of North America or the E-carrier system of Europe and other continents. The following table lists the common DS-series transmission rates and their T-series or E-series equivalents (when defined). For example, you can see that a T1 data transmission is equivalent to 24 DS-0 transmissions multiplexed together and can transmit data at a rate of 1.544 Mbps.

DS-Series Transmission Rates

<i>DS Type</i>	<i>Multiple of DS0</i>	<i>Data Rate</i>	<i>T-Series</i>	<i>E-Series</i>
DS0	1	64 Kbps	N/A	N/A
DS1	24	1.544 Mbps	T1	N/A
N/A	32	2.048 Mbps	N/A	E1
DS1C	48	3.152 Mbps	N/A	N/A
DS2	96	6.312 Mbps	T2	N/A
N/A	128	8.448 Mbps	N/A	E2
N/A	512	34.368 Mbps	N/A	E3
DS3	672	44.736 Mbps	T3	N/A
N/A	2048	139.264 Mbps	N/A	E4
DS4	4032	274.176 Mbps	N/A	N/A
N/A	8192	565.148 Mbps	N/A	E5

DS-1

Also known as DS1, a transmission standard for digital telecommunications.

Overview

A DS-1 circuit consists of 24 DS-0 circuits multiplexed together into a circuit. The bandwidth of a DS-1 circuit is 1.544 Mbps, and a common name for such an arrangement is a T1 line. DS-1 is also a typical signaling rate for frame relay links.

Implementation

DS-1 circuits can be implemented singly or multiplexed together to form fatter pipes for carrying data faster. Multiple DS-1 circuits can be bonded together to create NxDS-1 circuits. Here N can be from 2 up to 8, providing a maximum throughput of 12 Mbps. In this arrangement, the first DS-1 circuit is the one responsible for managing the link, and if this circuit goes down the entire link fails.

D

① Implementing DS-1

② Implementing NxDS-1

DS-1. Implementing DS-1 and NxDS-1 on a Frame Relay network.

NxDS-1 is typically used when you do not expect your data requirements to radically increase for several years. If you are expecting much faster growth in data rates, consider moving to DS-3 or fractional DS-3 instead of NxDS-1.

Issues

When you want to upgrade from DS-1 to NxDS-1, you typically need to give up your old DS-1 circuits and obtain all new ones. This is because carriers terminate single and multiplexed DS-1 circuits differently at their

end. Furthermore, it is a good idea to upgrade to the highest value of N you might require immediately because adding additional DS-1 circuits later could cause problems if these circuits follow different paths and experience different latencies at the multiplexor.

You may also need to upgrade your router if you move from DS-1 to NxDS-1. This is because the V.35 interface on most Cisco routers only supports speeds up to 3 Mbps, which corresponds to 2xDS-1. For higher speeds, obtain a router with High Speed Serial Interface (HSSI).

See Also: DS-0, DS-3, frame relay, High-Speed Serial Interface (HSSI), T1, V.35

DS-3

Also known as DS3, a transmission standard for digital telecommunications.

Overview

A DS-3 circuit consists of 672 DS-0 circuits multiplexed together into a circuit. The bandwidth of a DS-3 circuit is 44.736 Mbps, and a common name for such an arrangement is a T3 line.

Implementation

DS-3 circuits are typically connected to enterprise local area networks (LANs) using an Asynchronous Transfer Mode (ATM) switch. DS-3 is rarely available for frame relay links and is usually reserved for dedicated leased lines only.

DS-3 is usually available in several forms:

- **Channelized DS-3:** This consists of multiplexed DS-1 lines that terminate at the customer premises at a device called an M13 (DS-1 to DS-3 multiplexor). You can implement from 1 to 28 DS-1 circuits in channelized DS-3, which is cost-efficient because you pay only for what you need.
- **Fractional DS-3:** This is similar to channelized DS-3 but lets you add or remove bandwidth in 3-Mbps chunks (equivalent to a pair of DS-1 circuits).
- **Full DS-3:** In this scenario an M13 is not required, and the coax cable at the demarc point where the circuit enters the customer's wiring closet is simply connected directly to the router (only the most powerful routers support this arrangement).

Notes

Most companies do not have a need for DS-3, and a slower (and cheaper) alternative is NxDS-1, which uses multiplexed DS-1 circuits.

dual boot

A computer that can boot one of several operating systems by means of a startup menu.

Overview

An example of a dual boot configuration is a machine on which Windows 98 and then Windows 2000 has been installed. The user can utilize the Windows NT boot loader menu to choose which operating system to run at startup.

Windows 2000, Windows XP, and Windows .NET Server support dual booting with other operating systems, but this is neither recommended nor supported by Microsoft Corporation. Dual boot systems are typically used in hobbyist and test networks in which a variety of operating systems are used to test different networking functions or when the number of available machines is fewer than needed to perform the tasks.

Notes

The Windows 2000, Windows XP, and Windows .NET Server boot loader menus can include up to 10 operating systems.

Dual Tone Multiple Frequency (DTMF)

The audio signaling method used by Touch-Tone phones.

Overview

Each DTMF signal generated by pressing a key on a Touch-Tone phone generates two simultaneous audible

tones of different frequencies, as shown in the table below. The advantage of this scheme is that faster and better accuracy of tone recognition (and hence recognition of what number is dialed) is achieved than if single tones were used.

Frequencies of DTMF Signals

	697 Hz	770 Hz	852 Hz	941 Hz
1209 Hz	1	4	7	*
1336 Hz	2	5	8	0
1477 Hz	3	6	9	#

DTMF was developed by AT&T; the term Touch-Tone was originally an AT&T trademark.

Uses

Microsoft Corporation's Telephony Application Programming Interface (TAPI) can recognize and interpret Dual Tone Multiple Frequency (DTMF) signals, allowing Microsoft Windows-based applications to integrate with telephony. Some networking vendors also supply hardware devices called DTMF/ASCII converters, which convert DTMF tones directly into different ASCII characters, which can then be fed as input into a program that routes telephone calls accordingly.

duplex

A telecommunications term referring to bidirectional communication.

Overview

In full-duplex communication, both stations send and receive at the same time, and usually two communication channels are required. However, you can also achieve full-duplex communication using a multiplexing technique whereby signals traveling in different directions are placed into different time slots. The disadvantage of this technique is that it cuts the overall possible transmission speed by half.

In half-duplex communication, only one station can transmit at any given time while the other station receives the transmission. The opposite of duplex communication is simplex communication, which can occur only in one direction.

DVMRP

Stands for Distance Vector Multicast Routing Protocol, a multicast routing protocol based on the spanning tree algorithm.

See: Distance Vector Multicast Routing Protocol (DVMRP)

DWDM

Stands for dense wavelength division multiplexing, a multiplexing technology for achieving extremely high data rates over fiber-optic cabling.

See: dense wavelength division multiplexing (DWDM)

dynamic disk

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, a new kind of disk management technology for hard disks.

Overview

Dynamic disks are different from basic disks, which are disk systems that function similarly to earlier versions of Windows (basic disks are also supported by Windows 2000, Windows XP, and Windows .NET Server). Dynamic disks support advanced features such as online management, disk reconfiguration, and fault tolerance.

While basic disks are divided into partitions, a dynamic disk is divided into volumes. A simple volume consists of one or more regions of space on a dynamic disk (these regions need not be contiguous). Although a multidisk system using basic disks has a single partition table describing the data structure of all disks on the system, things are different with dynamic disks. When a system contains multiple dynamic disks, each dynamic disk reserves 1 MB of space at the end of the drive, and this space stores configuration information concerning all of the disks in the system. This provides a measure of fault-tolerance, for if one disk fails the configuration information is not lost concerning the other disks in the system.

When changes are made to a dynamic disk, such as extending a volume to add more space for storage, no reboot is required for the changes to take effect (basic

disks must be rebooted when changes are made). You can also use dynamic disks in hot-swappable systems to add or remove drives without requiring a reboot.

Uses

Dynamic disks are intended for use on servers where high-availability and fault tolerance are essential. Workstations gain little by using dynamic instead of basic disks, and dynamic disks are not supported on laptops since they would bring no benefit there.

Dynamic disks are not supported by removable drives such as Zip and Jaz drives, USB and firewire drives, SyQuest drives, and so on.

Dynamic disks also cannot be used on dual-boot systems, as earlier versions of Windows cannot recognize them even if they are formatted using FAT or FAT32.

Implementation

You create and manage dynamic disks in three ways:

- Use the Disk Management console to convert an existing basic disk to a dynamic one.
- Add a new drive to a system and configure it as a new dynamic disk.
- Import a dynamic disk from a different Windows 2000, Windows XP, or Windows .NET Server system into your own system.

Note that the only way to convert a dynamic disk back to a basic disk is to back up all your information, reinitialize the disk by creating partitions, and restore.

dynamic DNS (DDNS)

A feature of the Domain Name System (DNS) that enables DNS clients to automatically register their DNS names with name servers.

Overview

Ordinary DNS must be administered manually, with administrators typically making changes directly to zone files on name servers. Information in zone files needs to be updated whenever a new host appears on the network or a host leaves, so the more the network

D changes, the more work this entails for DNS administrators. Once a zone file is updated on a name server, the updated information is then propagated to other name servers by zone transfers, which are typically scheduled to occur periodically.

Dynamic DNS (DDNS) lets changes to zone files to be made automatically instead of manually, saving DNS administrators the labor-intensive work of maintaining up-to-date zone information concerning all hosts on their network. To accomplish this, DDNS uses a process called dynamic updates outlined in RFC 2136.

Uses

DDNS in Microsoft Windows 2000, Windows XP, and Windows .NET Server is used in two scenarios:

- **Registration of DHCP clients:** When DDNS is enabled and used in conjunction with DHCP, Windows 2000, Windows XP, and Windows .NET Server machines that initialize on the network dynamically acquire an Internet Protocol (IP) address and then automatically register their DNS name and IP address with the DNS server by adding an A record for the client to the name server's zone file.
- **Registration of domain controllers.** When a domain controller boots up for the first time, it registers an SRV record with the DNS server. This SRV record is needed by DNS clients so they can locate the domain controller in order to log on to the network.

Implementation

DDNS is supported by the Windows 2000 and Windows .NET Server implementation of DNS and greatly simplifies the administration of DNS zone information in Windows 2000 and Windows .NET Server networks. DDNS is recommended for Windows 2000- and Windows .NET Server-based networks because Active Directory directory service uses DNS as its name locator service for locating hosts on the network and DDNS also reduces the chances of error that occur when DNS is administered manually.

Dynamic update lies at the heart of Active Directory because domain names in Windows 2000 and Windows .NET Server are also DNS names. For example, northwind.microsoft.com can be both a legal DNS

name and the name of a Windows 2000 domain. When DNS is integrated with Active Directory and configured for dynamic updates, the root zone and forward lookup zones are created and configured automatically for each domain, but administrators must enable and manage reverse lookup zones.

DDNS is similar to ordinary DNS in that zone update operations occur using primary or master servers only. DDNS, however, allows primary servers to receive updates initiated by a specified list of "authorized servers," which can include secondary zone servers, domain controllers, and other servers that perform name registration services, such as Windows Internet Name Service (WINS) or DHCP servers.

Most name servers on the Internet either do not yet support or are configured not to support DDNS because of the extra security issues involved when using it. DDNS is currently most popular in corporate networks using Windows 2000 and Active Directory.

Notes

You can use the DNS Manager snap-in for the Microsoft Management Console (MMC) to enable Active Directory integration on an existing DNS server. The zone file information will be written into Active Directory.

Note that by default DDNS on Windows 2000 and Windows .NET Server does not automatically scavenge (purge) old resource records for clients no longer on the network—you need to manually enable and schedule scavenging.

Dynamic Host Configuration Protocol (DHCP)

A protocol that enables the dynamic configuration Internet Protocol (IP) address information for hosts on an internetwork.

Overview

Dynamic Host Configuration Protocol (DHCP) is an extension of the bootstrap protocol (BOOTP). DHCP is implemented as a client-server protocol that uses DHCP servers and DHCP clients.

Dynamic Host Configuration Protocol (DHCP). How a DHCP client leases an IP address from a DHCP server.

A DHCP server is a machine that runs a service that can lease out IP addresses and other Transmission Control Protocol/Internet Protocol (TCP/IP) information to any DHCP client that requests them. For example, on Microsoft Windows 2000 servers, you can install the Microsoft DHCP Server service to perform this function. The DHCP server typically has a pool of IP addresses that it is allowed to distribute to clients, and these clients lease an IP address from the pool for a specific period of time, usually several days. Once the lease is ready to expire, the client contacts the server to arrange for renewal.

DHCP clients are client machines that run special DHCP client software enabling them to communicate with DHCP servers. All versions of Windows include DHCP client software, which is installed when the TCP/IP protocol stack is installed on the machine.

DHCP clients obtain a DHCP lease for an IP address, a subnet mask, and various DHCP options from DHCP servers in a four-step process:

- 1 DHCPDISCOVER:** The client broadcasts a request for a DHCP server.
- 2 DHCPOFFER:** DHCP servers on the network offer an address to the client.
- 3 DHCPREQUEST:** The client broadcasts a request to lease an address from one of the offering DHCP servers.
- 4 DHCPACK:** The DHCP server that the client responds to acknowledges the client, assigns it any configured DHCP options, and updates its DHCP database. The client then initializes and binds its TCP/IP protocol stack and can begin network communication.

DHCP lease renewal consists only of steps 3 and 4, and renewal requests are made when 50 percent of the DHCP lease time has expired.

Implementation

When you implement DHCP on a network, you should consider the following:

- DHCP servers do not share their database of leased IP addresses, so if your network has more than one DHCP server, be sure that their DHCP scopes do not overlap.
- Assign DHCP options to the DHCP server if clients need them.
- Assign static IP addresses to non-DHCP clients, and exclude these addresses from the scope on the DHCP server if necessary.
- Assign static IP addresses to all servers on your network or assign them DHCP client reservations on the DHCP server to ensure that they always lease the same IP address.
- Configure DHCP relay agents if one DHCP server must serve hosts on several subnets.

Marketplace

Although network operating system platforms such as Microsoft Windows 2000 and Novell NetWare include their own DHCP services, enterprise network architects may also want to consider self-contained DHCP applications from third-party vendors as well. Some of these third-party DHCP products include additional features such as query and reporting tools that make them attractive to use in an enterprise environment. Some examples of such products include Shadow Ipserver from Network TeleSystems (recently acquired by Efficient Networks), IP AddressWorks from Process Software, NetID from Nortel Networks, network Registrar from Cisco Systems, and Meta IP from CheckPoint Software Technologies.

Dynamic HTML (DHTML)

A proposed World Wide Web Consortium (W3C) standard developed by Microsoft Corporation for creating interactive multimedia Web content.

Overview

Developers can use Dynamic HTML to make Web pages look and behave more like typical desktop applications. Dynamic HTML supports features such as

- Document Object Model (DOM), a standard whereby every element of a Web page is exposed for scripting. Each element on a Hypertext Markup Language (HTML) page can function as an object that can be modified using scripts and other programs. For example, Dynamic HTML can make the appearance of an object on a Web page change during an onmouseover or onclick event.
- Cascading Style Sheets (CSS) positioning, which allows HTML content developers to control the style and layout of objects on a Web page using style sheets. These style sheets can then be cascaded to define different levels of precedence.
- Dynamic Content and Dynamic Styles, which HTML content developers can use to dynamically change the content or style of every HTML element on a Web page based on mouse events or other forms of user interaction.
- Data Binding, which integrates data with HTML elements. For example, table rows can be automatically generated from data records and data-bound fields.

dynamic-link library (DLL)

A file containing executable routines that can be loaded on demand by an application.

Overview

Dynamic-link libraries (DLLs) offer the advantage of providing standard services for many different calling applications, and they simplify and modularize

application development by providing component-based services. DLLs are loaded into RAM only when needed by the calling application, which reduces the memory requirements of large applications. DLLs are files that have the extension .dll.

dynamic packet filtering

The process of filtering packets according to real-time criteria.

Overview

Dynamic packet filtering is a feature of firewalls, routers, and proxy servers such as Microsoft Proxy Server. Using dynamic packet filtering, a system can

- Determine dynamically whether to accept a packet from the Internet while minimizing the number of exposed ports in both directions and the length of time the port is open to the Internet
- Drop all packets on an external interface by default

Implementation

In Microsoft Proxy Server, dynamic packet filtering involves two components:

- **Packet Filter Driver:** This component talks directly to the external network interface
- **Packet Filter Manager:** This component provides the high-level interface for interaction between Proxy Server services and the driver

In a typical scenario, a client with the Winsock Proxy client might attempt to connect to an Internet server using Telnet. The Winsock Proxy client intercepts the Telnet connection request and remotes the request to the Winsock Proxy server, which verifies that the client has proper Microsoft Windows NT permissions to use Telnet to access servers on the Internet and opens a local socket. The Winsock Proxy server then informs the Packet Filter Manager that an outbound connection request from the socket to a remote Telnet service has been approved, and the Packet Filter Manager orders the Packet Filter Driver to open the socket and the

Winsock Proxy server to start a Telnet session on behalf of the client. When the Winsock Proxy determines that the client has closed the Telnet session, it tells the Packet Filter Manager to close the socket and thus blocks any further packets from the remote system.

dynamic routing

A routing mechanism for dynamically exchanging routing information among routers on an internetwork.

Overview

Dynamic routing operates using a dynamic routing protocol, such as Routing Information Protocol (RIP) or Open Shortest Path First (OSPF) Protocol. Routers that use dynamic routing are sometimes called dynamic routers.

For dynamic routing to work, the routing protocol must be installed on each router in the internetwork. The routing table of one router is manually seeded with routing information for the first hop, and then the routing protocol takes over and dynamically builds the routing table for each router. Dynamic routers periodically exchange their routing information so that if the network is reconfigured or a router goes down, the routing tables of each router are automatically modified accordingly.

Advantages and Disadvantages

Dynamic routers are much simpler to administer than static routers, but they are sometimes less secure because routing protocol information can be spoofed. If the network is reconfigured or a router goes down, it takes a certain period of time for this information to propagate between the various routers on the network. This router reconfiguration process is usually referred to as convergence. However, getting a dynamic router up and running is often as simple as connecting the interfaces and turning it on—routes are discovered automatically by communications with other routers on the network. Dynamic routers are also fault-tolerant, for when a router fails the other routers soon learn about it and adjust their routing tables accordingly to maintain communications across the network.

Using dynamic routing protocols also creates additional network traffic due to routing table updates and exchanges, and different dynamic routing protocols offer their own advantages and disadvantages in this regard.

Dynamic routers cannot exchange information with static routers. To configure static and dynamic routers to work together on the same internetwork, you must add manual routes to the routing tables of both types of routers.

Notes

You can configure a multihomed Microsoft Windows 2000 or Windows .NET Server server as a dynamic RIP router by selecting Enable IP Forwarding on the Routing tab of the Transmission Control Protocol/Internet Protocol (TCP/IP) property sheet and then using the Services tab of the Network property sheet to add the RIP for Internet Protocol (IP) service to the server. Another example of a dynamic router is a multihomed computer running Windows 2000 Server with Routing and Remote Access Service (RRAS) and either RIP or OSPF configured.

dynamic routing protocol

A protocol that enables dynamic routing to be used to simplify management of a routed network.

Overview

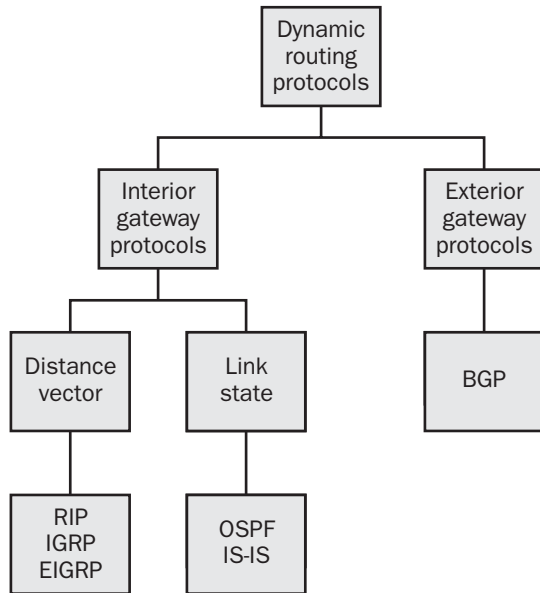

If we focus on Internet Protocol (IP) routing, which is the standard for the Internet and most corporate networks, several kinds of dynamic routing protocols can be deployed. These routing protocols can be classified in a hierarchical scheme as shown in the illustration.

First, dynamic routing protocols can be one of two types:

- **Interior Gateway Protocols (IGPs):** These are used to manage routing within autonomous systems (ASs). IGPs are further classified below.
- **Exterior Gateway Protocols (EGPs):** These are used to manage routing between different ASs. The de facto example of an EGP is the Border Gateway Protocol (BGP) used on the Internet.

D

Dynamic routing protocol. Classification of popular dynamic routing protocols.

IGPs can be further classified according to the type of algorithm used to build and distributed routing table information. Specifically, IGPs can employ the

- **Distance vector routing algorithm:** Examples of dynamic routing protocols that use this algorithm include Routing Information Protocol (RIP), Interior Gateway Routing Protocol (IGRP), and Enhanced Interior Gateway Routing Protocol (EIGRP).
- **Link state routing algorithm:** Examples of dynamic routing protocols that use this algorithm include Open Shortest Path First (OSPF) and Integrated System to Integrated System (IS-IS).

dynamic volume

In Microsoft Windows 2000, Windows XP, or Windows .NET Server, a volume created on a dynamic disk.

Overview

Windows 2000, Windows XP, and Windows .NET Server support several kinds of dynamic volumes including

- **Simple volumes:** These consist of one or more regions of contiguous space on a single drive.
- **Spanned volumes:** These consist of one or more regions of contiguous space from two or more drives.
- **Striped volumes:** RAID 0 or disk striping using dynamic disks.
- **Mirrored volumes:** RAID 1 or disk mirroring using dynamic disks.
- **RAID 5 volumes:** Disk striping with parity using dynamic disks.

You can create dynamic volumes using the Disk Management portion of the Computer Management administrative tool. You can create dynamic volumes only on dynamic disks.

e-business

Refers generally to the process of using the Internet for conducting key activities of your business.

In the new Internet economy two terms are generally confused:

- **e-commerce:** This refers specifically to the process of buying and selling goods and services over the Internet.
- **e-business:** This more general term may include e-commerce activity, but also includes using the Internet for additional core business processes, including management of supply-line services, customer relations, and human resources.

E-commerce is generally B2C (business-to-consumer) in orientation, but e-business includes B2B (business-to-business) activities that join separate businesses entities over the Internet into value chains using negotiated agreements. In an e-business scenario, the basic activities of business (including invoicing, transactions, and procurement) are all performed electronically over the Internet. Technologies such as Electronic Data Interchange (EDI) and Extensible Markup Language (XML) are employed to facilitate the exchange of information between business

partners. Because the Internet is a public network, security is a high priority for e-business, and technologies such as virtual private networks (VPNs) and Internet Protocol Security (IPsec) are used to ensure the privacy, integrity, and authenticity of electronic business transactions.

In addition to businesses forming their own private negotiated business arrangements, a large number of public and private e-business marketplaces have emerged in the last few years to facilitate B2B relationships. An example is the Microsoft Market, which is Microsoft Corporation's internal Web-based procurement system.

For companies migrating from the old brick-and-mortar model to the new e-business model, there are many advantages incurred in the move. These include lowered procurement costs, shorter business cycles, more efficient customer service, and new kinds of sales opportunities.

E-carrier

The digital telecommunications services backbone system of Europe, a format standardized by the International Telecommunication Union (ITU).

Overview

The E-carrier service rates are specified by the organization CEPT (Conférence Européenne des Administrations des Postes et des Télécommunications, or European

Conference of Postal and Telecommunications Administrations). The most popular of these services, E1, is also the slowest. E1 transmits data at speeds of up to 2.048 megabits per second (Mbps) over two pairs of twisted wires. It consists of 32 separate 64-kilobits-per-second (Kbps) DS-0 channels multiplexed together, each of which can carry either a voice conversation or a stream of data. E1 is sometimes referred to as 2-Meg.

E

E-carrier. Connecting to an E-carrier service.

E-carrier transmissions are graded E1, E2, and so on, in order of increasing transmission speeds. These different service grades are multiples of the basic DS-0 data transmission rate, similar to the T-carrier system of North American telecommunications carriers. The E-carrier transmission rates are shown in the table included in the article “DS-0” elsewhere in this book. E-carrier lines use 8 bits per channel for encoding signals and do not rob bits for control signals as T-carrier lines do.

E-carrier services were developed in the 1970s and became widely available in the 1980s. E-carrier services can be used for wide area network (WAN) connections, for high-speed Internet connections, for private videoconferencing services, and for public frame relay services. E-carrier services are generally available wherever the parallel T-carrier services are not.

Notes

If the E1 service entering your customer premises needs to connect directly to a different building, you have two options. First, you could have the service provider extend the E1 line to the other building, thus moving the demarcation point (termination point) of the line. This could be costly, however. A simpler solution might be to connect the E1 line to a fiber-optic line driver, install a fiber-optic cable from the line driver to a similar driver in the other building, and then connect the remote line driver to your E1 equipment (see diagram).

EDGAR

Stands for Electronic Data Gathering, Analysis, and Retrieval, an online document management system used by the U.S. Securities and Exchange Commission (SEC).

Overview

EDGAR is an online service with two main functions:

- To provide corporations with an electronic method for filing public disclosures such as quarterly earnings statements, annual reports, and so on. This is the “private” side of EDGAR, and companies currently file this information by means of the Web, through virtual private network connections (VPN) or through dial-up modem connections.
- To provide a clearinghouse that allows individuals and organizations to view archived reports of publicly traded companies. This is the “public” side of EDGAR, which receives almost 1 million visitors daily.

EDGAR was upgraded in 2000 from its older OS/2 system to Microsoft Windows NT, and the SEC is looking into ways to use Extensible Markup Language (XML) to help EDGAR submissions search for information in its vast database more easily.

See: *Enhanced Data Rates for Global Evolution (EDGE)*

edge router

A device in an Asynchronous Transfer Mode (ATM) network that routes data between an ATM backbone network and local area networks (LANs).

Overview

Edge routers can be used to translate Ethernet or Token Ring data for transmission over ATM backbones. This allows ATM to be used as a backbone for connecting multiple LANs into a metropolitan area network (MAN) or wide area network (WAN).

Edge router. Using an edge router to connect LANs to an ATM backbone.

An alternative and more commonly used configuration is to connect LAN networking equipment directly to

ATM backbone switches, which provide points of contact with an ATM provider's backbone network.

An edge router can function as an ATM switch and provide routing capabilities for LAN networking protocols—all in one hybrid device.

eDirectory

The latest version of Novell Directory Services (NDS).

Overview

Novell eDirectory is the new name for NDS version 8.x and emphasizes the enhanced Internet functionality of NDS. Novell eDirectory is a key part of Novell's "One Net" strategy and includes the following enhancements over previous versions of NDS:

- Native support for Lightweight Directory Access Protocol version (3) (LDAPv3) and LDAP Data Interchange Format (LDIF)
- An internal schema that more closely conforms to the LDAPv3 standard than earlier versions
- Support for enhanced Domain Name System (DNS) naming conventions
- Extensible support for management using the ConsoleOne utility
- Increased scalability to support more than a billion objects per directory tree

Novell eDirectory is available for the Novell NetWare, Microsoft Windows NT, Windows 2000, UNIX, AIX, Compaq Tru64 UNIX, Solaris, and Linux platforms. The current version is eDirectory 8.5.

effective permissions

In Microsoft Windows 2000, Windows XP, and Windows .NET Server, the cumulative permissions a user has for accessing a resource based on a user's individual permissions, group permissions, and group membership.

Overview

The effective permissions a user experiences in trying to access a file or folder depend on the various permissions granted to the user expressly or by virtue of membership in a particular group. When a permissions conflict exists between one group and another, or between the user and a group, rules are applied that resolve the issue.

In networks based on Windows 2000, Windows XP, and Windows .NET Server, calculation of effective permissions can be determined using three simple rules:

First, if a user belongs to two (or more) groups, and these groups have different NTFS file system (NTFS) standard file permissions on a given file, the user's ability to access the file both locally and over the network is determined as follows: the effective NTFS permission is the least restrictive (most permissive) NTFS standard permission. For example,

$\text{read (NTFS)} + \text{change (NTFS)} = \text{change (NTFS)}$

The exception to this is that the no-access permission overrides all other permissions. For example,

$\text{read (NTFS)} + \text{no access (NTFS)} = \text{no access (NTFS)}$

Second, if a user belongs to two (or more) groups, and these groups have different shared folder permissions on a given shared folder, the user's ability to access the shared folder over the network is determined as follows: the effective shared folder permission is the least restrictive (most permissive) shared folder permission. For example,

$\text{read (shared folder)} + \text{change (shared folder)} = \text{change (shared folder)}$

The exception to this is that the no-access permission overrides all other permissions. For example,

$\text{read (shared folder)} + \text{no access (shared folder)} = \text{no access (shared folder)}$

Third, when a user attempts to access a folder or file over a network that has both NTFS permissions (the first example) and shared folder permissions (the second example) configured on it, the effective permission is the most restrictive (least permissive) permission. For example,

$\text{read (NTFS)} + \text{change (shared folder)} = \text{read (combined)}$

EIA/TIA wiring standards

Standards for commercial and telecommunications wiring developed by the Electronic Industries Alliance (EIA) and Telecommunications Industry Association (TIA).

Overview

The EIA/TIA wiring standards actually comprise a group of standards covering different aspects of premise cabling and other wiring practices. These standards include

- **EIA/TIA 570:** Residential/Light Commercial Wiring Standard
- **EIA/TIA 568A:** Commercial Building Telecommunications Cabling Standard
- **EIA/TIA 569:** Commercial Building Standard for Telecommunications Pathways and Spaces
- **EIA/TIA 606:** Design Guideline for Administration of Telecommunications Infrastructure in Commercial Buildings
- **EIA/TIA 607:** Commercial Building Grounding and Bonding Requirements for Telecommunications

When installing wiring for your network, be sure to follow the EIA/TIA standards to ensure that your network functions as expected and that it complies with all local and state building codes and regulations.

The EIA/TIA wiring standards are also supported by the American National Standards Institute (ANSI).

election

The process of selecting a new master browser from a Microsoft Windows network's potential browsers.

Overview

If a client machine cannot locate a master browser on the network in Windows NT, Windows 2000, Windows XP, or Windows .NET Server, it initiates an election to select a new master browser. Elections ensure that a master browser is always available on the network, since the absence of a master browser means that clients will be unable to locate and access network resources such as shared files and folders.

If a client machine cannot locate a master browser on the network, it broadcasts an election datagram. When a machine that is a potential browser receives this datagram, it examines the election criteria in the datagram. If its election criteria are better than those of the datagram's sender, the potential browser broadcasts its own election datagram and an election is declared to be in progress. The election criteria for becoming a master

browser include many factors, such as the machine's operating system, version, and role. Eventually, one potential browser prevails over other machines on the network because it has superior election criteria, and the election ends.

Notes

Elections also occur when domain controllers are restarted.

electromagnetic interference (EMI)

Electrical noise induced in cabling by the presence of nearby electrical equipment such as motors, air conditioners, fluorescent lights, and power lines.

Overview

Electromagnetic interference (EMI) can interfere with the transmission of signals and render network communications unreliable or impossible. EMI is only a problem if copper cabling is used—fiber-optic cabling is immune to sources of EMI.

EMI is caused when the changing electromagnetic fields generated by one cable induce extraneous currents or interference in adjacent or nearby cables. EMI in copper cabling can be reduced to acceptable levels by

- Avoiding bunching of unshielded cabling
- Keeping all cabling away from power cords and transformers
- Using shielded twisted-pair (STP) cabling instead of unshielded twisted-pair (UTP) cabling
- Enclosing cabling in external mesh or wire shielding
- Properly grounding electrical equipment and external shielding
- Taking care not to excessively untwist the terminating ends of twisted-pair cabling

EMI can be a greater concern in heavy industrial settings where high voltages and equipment, such as motors and generators, produce high levels of electrical noise. Using coaxial cabling in these settings affords

greater resistance to the effects of EMI than using twisted-pair cabling. Fiber-optic cabling is an even better solution in heavy industrial settings because it is wholly resistant to EMI. (Changing electromagnetic fields has no effect on the light waves traveling along a glass fiber.)

Electronic Business Extensible Markup Language (ebXML)

An Extensible Markup Language (XML) standard that allows businesses to locate each other on the Internet, form partnerships, and exchange business information.

Overview

The ebXML standard specifies protocols and mechanisms that allow businesses to use the Internet and XML to create and centrally store business profiles of their companies, find other companies providing desired types of business services, enter into partnership agreements, and collaborate through electronic document exchange such as invoicing, receipts, shipping notices, and so on. The ebXML standard is designed to promote electronic business between companies of any size located anywhere in the world using a common infrastructure (the Internet) and a common language for sharing structured information (XML).

The ebXML standard provides open specifications for how companies define their business processes, create and register company profiles and business processes, enter into trading agreements, and exchange business information using XML messages. Businesses can use ebXML to exchange business information with each other without being concerned about the structure of the underlying data processes of other partners in the process.

The ebXML standard is an initiative of the Organization for the Advancement of Structured Information and Standards (OASIS) and a United Nations (UN) standards body called UN/CEFACT (United Nations Center for Trade Facilitation and Electronic Business). Development of the ebXML standard began in 1999 with the backing and support of IBM, Sun Microsystems, BEA Systems, Commerce One, and a number of other companies.

Implementation

The ebXML standard specifies a set of protocols for packaging business information as high-level messages and routing them to required destinations. Any kind of business transactional message can be encapsulated by ebXML, including electronic data exchange (EDI) X12 messages, EDIFACT messages, XML messages, or some proprietary transactional message schemes.

The ebXML protocol suite is modular in architecture and consists of several protocols that enable encapsulation, transport, and routing of XML messages. To help promote uniform standards in the B2B arena and prevent fracturing of the market, the ebXML group has agreed not to compete with the developers of Simple Object Access Protocol (SOAP), but instead to incorporate SOAP 1.1 as its underlying protocol for enabling remote activation of software components over the Internet. SOAP 1.1 was developed by Microsoft in conjunction with IBM.

electronic data interchange (EDI)

The industry standard format for exchanging business information electronically.

Overview

Electronic data interchange (EDI) is a well-established standard by which companies can exchange business data and perform financial transactions using electronic means. EDI is commonly used by large companies to link their financial systems to supply-chain partners to automate and speed procurement for assembly line processing.

Some analysts estimate there are more than 300,000 companies worldwide using some form of EDI to streamline their procurement processes.

EDI is a compact format that allows information to be structured in a way that it can easily mapped to traditional business forms such as invoices, purchase orders, receipts, and so on. EDI is used mostly by large companies that process high volumes of business transactions, and it can save these companies considerable costs by greatly reducing paperwork, mail, and fax charges.

History

EDI was born in the 1970s when large companies such as Kmart Corporation and Sears, Roebuck, and Company saw the need for a standard way of exchanging business information with trading and supply-chain partners. Developing custom solutions for electronic business document exchange was costly, so the Data Interchange Standards Association (DISA) was formed, consisting of government, transportation, and private sector companies, to address this issue. In 1979, EDI was approved as an American National Standards Institute (ANSI) standard called X.12. The X.12 standard defines the data dictionary used by EDI for formatting messages for standard communications between business partners. Other standards competing with EDI for electronic exchange of business documents were concurrently developed, but by the mid-1980s, X12 had become a widely recognized standard and EDI began to be widely deployed, especially in large companies.

Architecture

The basic unit of an EDI transmission is the message, which consists of a transaction set with a header and footer attached. An EDI message adheres to a standard format called the Electronic Data Interchange for Administration, Commerce, and Transport (EDIFACT) protocol.

An EDI transaction set is roughly equivalent to a typical business form, such as a purchase order, and consists of data segments, each containing various fields delimited by some character. These fields represent individual elements of the business transaction, such as company name, account number, quantity, and so on; they are formatted according to a standard code. This code is then

implemented as a map between your business application's data fields and the type of EDI standard appropriate to the transaction performed.

EDI transactions are typically processed in batch form. Some forms of interactive EDI have emerged, but the basic architecture of EDI was designed around the concept of mainframe batch processing.

Implementation

EDI-enabled systems communicate through translation software that formats the data into standard EDI encoding format. This information is then exchanged using one of several methods:

- Using a dedicated leased line between the business partners. This method is expensive but is often employed by large enterprises that have high volumes of EDI transactions to process.
- Using a dial-up modem connection between business partners. This method saves costs by using EDI's strength batch-processing strength. Transactions can be queued and then sent as a batch job over a dial-up connection to save money. Small to medium-sized supply-chain partners often use this method to exchange business information with a large company purchasing their goods or services.
- Through an external third-party value-added network (VAN) service provider that acts as a clearinghouse for EDI transactions. The VAN processes EDI messages and routes them to the appropriate electronic mailbox for the destination business partner, who can then retrieve the EDI messages from the mailbox and process the transactions using business applications. The VAN is responsible for message routing, delivery, security, auditing, and archiving. This approach has grown in popularity over the last decade and is probably the most popular EDI implementation in use today.

A newer method used by small suppliers to exchange EDI information with large manufacturers is Web-enabled EDI. Typically, a VAN will offer a Web forms front end that the supplier can use to submit invoices and issue receipts to the purchasing company. This saves suppliers considerable costs over having to build

EDI into the back end of their business processes but involves additional expenditure of manual labor in entering data into the forms. Nevertheless, this is a popular scheme that has become widely implemented in some sectors.

Advantages and Disadvantages

Besides its entrenched usage in the big business marketplace, particularly in government, manufacturing, transport, and warehouse sales, EDI has other advantages over such emerging technologies as Extensible Markup Language (XML). For one thing, EDI messages are compact, using a highly condensed format that makes them difficult to read. XML messages, by comparison, are plain text and tend to be much larger than EDI messages. As a result, small businesses that use dial-up connections for exchanging business information with their purchasers and suppliers can save online costs using EDI compared to XML. Because EDI mainly uses leased lines, the technology is intrinsically more secure than a technology such as XML that uses an insecure public network such as the Internet. However, by employing virtual private network (VPN) technology for tunneling over the Internet, the level of security in using XML has been made comparable to that of EDI.

While the costs of implementing EDI or leasing VAN services might at first glance seem higher than XML, this is not actually true because XML is not yet an established standard for communication of business transactions. In particular, XML has the same hidden costs as EDI due to the expense of building either system into a company's back-end business processes, which usually requires much customized programming and tinkering.

EDI's disadvantages are more perception than reality. That EDI is difficult to implement is acknowledged, but so is any translation system that must be deeply integrated into the back end of a company's business software, and nowadays EDI-enabled Enterprise Resource Planning (ERP) and customer relationship management CRM systems are commonly available, as are tools for helping developers custom-build EDI into existing business processes. Another perceived disadvantage of EDI is that it is complex and difficult to learn, but most EDI programmers would disagree with this assessment.

Marketplace

Some of the bigger VANs in the EDI marketplace include GE Information Services and IBM's Advantis. General Electric also offers a Web-based EDI service called GE TradeWeb, which provides companies with browser-based access to a library of EDI-enabled Web forms and an EDI mailbox for exchanging transactions with their business partners. Another player in this market is Sterling Commerce with its Gentran Web Suite, which uses Microsoft ActiveX technologies.

For the foreseeable future, both EDI and XML are expected to coexist, and as a result efforts are under way by both standards bodies and vendors to harmonize the two. Vitria Technology offers a kind of universal translation system for changing EDI information into XML and vice versa. General Electric is implementing the XMLSolutions Business Integration Platform to streamline its online procurement system. Another player in this hybrid EDI/XML service provider market is Paper-Free Systems, now acquired by Sybase.

Prospects

Some analysts view the emergence of XML as a threat to the very existence of EDI, supposedly relegating EDI to the arena of legacy systems. This is hardly the case, and most of the electronic business world still gets by using EDI. However, XML has some advantages over EDI; namely, it is more flexible, easier to work with, and more open in its specifications. On the other hand, just as there are different flavors of EDI that hinder interoperability, XML itself has more than 100 different variants, and it might take an initiative such as ebXML (Electronic Business Extensible Markup Language) to bring order to the XML chaos and make XML a truly viable alternative to EDI.

Most large companies are somewhat reluctant to migrate wholesale from EDI to XML. Besides the considerable investment they have already made in EDI systems and the "if it ain't broke, don't fix it" attitude that results, a big concern is the reliability of using XML for exchange of business information over the Internet. Because large businesses usually implement EDI using leased lines, carriers can provide these companies with service-level agreements (SLAs) guaranteeing minimal downtime.

The Internet is another factor, however, and it is hard to guarantee bandwidth and availability for information transmitted over the Internet. For batch processing of EDI transactions this is not a big issue, but for companies with delay-sensitive assembly-line processes that use real-time EDI for procurement of direct materials, the XML/Internet combination does not offer the same guarantees as the leased-line/VAN implementations of EDI. As a result, large companies that depend on EDI have been reluctant to open their supply chains to replace EDI with XML, and many are taking a wait-and-see attitude, believing that if they fall behind in the short run they can always use their deep pockets to catch up in the long run.

Electronic Industries Alliance (EIA)

The main trade organization representing the U.S. high-tech community.

Overview

The Electronic Industries Alliance (EIA) was founded in 1924 as the Radio Manufacturers Association. The EIA plays an important role in enabling U.S. electronics producers to be competitive by developing technical standards, hosting trade shows and seminars, performing market analyses, and facilitating relations with the government. The EIA represents a broad spectrum of U.S. electronics manufacturing interests.

The EIA is organized along the lines of specific electronic products and markets, with each sector, group, or division having its own board of directors and its own agenda for enhancing competitiveness. Major divisions include the components, consumer electronics, electronic information, industrial electronics, government, and telecommunications divisions.

An important computer networking function of the EIA is the series of standards for residential and commercial

network cabling that are collectively known as the EIA/TIA wiring standards. Individuals and companies installing cabling for computer networks must follow these standards to meet government legal and safety requirements.

electronic tape vaulting

The practice of backing up data directly to a remote backup facility.

Overview

Classic backup procedures involve backing up data regularly to network tape drives and libraries. In addition, daily copy backups are made of critical business data on servers and these tapes are taken off-site to a secure storage facility. When a disaster occurs, recovery using these off-site daily copies typically takes 48 to 72 hours because the hardware failure must be repaired or the server replaced, the operating system installed, and tapes shipped in from the off-site storage location. Some data is typically lost permanently under this scenario because the tapes are written only once a day but business transactions take place continually.

Electronic tape vaulting, or e-vaulting, is a technique that helps make recovery times faster and restores more up-to-date. In a typical scenario, e-vaulting supplements an existing backup plan similar to the one described above. Information written to local storage on servers is also transmitted over the network through a wide area network (WAN) link to a remote e-vaulting site, where it is written to tape. Data can be e-vaulted periodically (once an hour, for example), or even continuously as each transaction occurs. This transactional information, coupled with traditional daily copy backups, allows databases and other business information to be restored with little or no data loss.

Marketplace

Large enterprises have been using e-vaulting for some time, but recently with the proliferation of storage service providers (SSPs) even small to medium-sized businesses can lease e-vaulting services from a provider. An

example of such a service is provided by CNT, a specialist in storage area networking and other storage technologies, and Iron Mountain, a global leader in records management services. Using UltraNet, CNT's storage networking solution, a company can e-vault information incrementally to Iron Mountain's tape vaulting sites.

Notes

E-vaulting can also be used to back up data directly to mirror servers running at remote locations controlled either by the company itself or by storage service providers. This form of e-vaulting is more properly called mirroring.

e-mail

Stands for electronic mail; any system for electronically sending and receiving messages.

Overview

E-mail is arguably the technology that has had the greatest impact on how companies conduct businesses in modern times. E-mail has become the lifeblood of business, with some analysts estimating that fully one-third of all business-related information resides on mail servers, users' personal folders, and mail archiving systems.

E-mail is used for virtually every type of business communication, including marketing, invoicing, and customer service. E-mail saves businesses millions of dollars through the elimination of costly paper contracts, invoices, and receipts. E-mail also costs businesses millions of dollars in wasted time dealing with spam (unsolicited commercial e-mail) and undoing the effects of e-mail viruses. Despite these negative aspects, however, most companies would be at a standstill if their e-mail systems went down.

Estimates suggest that the number of commercial and private e-mail mailboxes globally was more than 500 million in 1999 and may well top 1 billion by the end of 2002. With the advent of wireless messaging, this figure may increase much more rapidly in the next few years. E-mail today is what the telephone was at the beginning of the century—a technology that shaped the evolution of business and commerce worldwide.

History

While e-mail had its roots in the early 1970s with the UNIX community and ARPANET, the first widely-used commercial e-mail system was the IBM mainframe host-based system called PROFS. Early e-mail systems were purely text-based and were expensive to deploy and complex to maintain, but they had an immediate impact on business.

With the move from mainframe systems to a client/server environment in the 1980s, a new breed of e-mail system arose called workgroup mail or LAN mail. Notable products in this area included Microsoft Mail, Lotus cc:Mail, and Novell GroupWise. Over time, these were replaced with collaborative systems that allowed users to exchange not only messages but also schedule and task information. Popular examples of these third-generation systems included Microsoft Exchange and Lotus Notes.

While these developments were occurring, efforts were under way to develop global standards for electronic messaging. These efforts resulted in two main systems: Simple Mail Transfer Protocol (SMTP), developed by the Internet community, and X.400, developed by the International Telecommunication Union (ITU). X.400 rapidly became a popular messaging format that is still used in parts of Europe, but SMTP mail, which was developed in the United States as part of the ARPANET project, eventually superseded X.400 and now enjoys worldwide popularity and acceptance as the universal e-mail system. Messaging and collaboration platforms, such as Microsoft Exchange, now support SMTP by default.

Implementation

Early local area network (LAN) mail systems such as Microsoft Mail and Lotus cc:Mail were essentially passive systems where the mail server was nothing more than a set of folders for containing users' mail. It was up to the mail client to deliver messages to the server and retrieve waiting messages. All processing was thus done by the client, which would periodically poll the server to see if any mail was waiting for it to download. These systems were cheap and easily set up and maintained, but they scaled poorly and had difficulty supporting more than a few hundred users effectively.

The next evolution of e-mail was client/server messaging. Here the passive mail server was replaced by an active server that contacted the client when mail was ready to be picked up. This push model of message delivery was more effective than the old pull model of constant server polling by the client, and it also made messaging more secure. In a client/server system, the client and the server both share the processing and transport of messages.

The X.400 messaging standards introduced a set of standard terminology and concepts into the messaging arena. The most notable of these new terms was MTA (message transport agent or mail transport agent), which was responsible for routing, or forwarding, messages across the network to its destination mail server. A complex messaging system would have a number of MTAs handling mail delivery. In the UNIX world where SMTP mail was born, a popular MTA was developed called Sendmail, which is still widely used on the Internet. Early UNIX mail clients such as Pine and Elm soon became popular, especially at universities and among government researchers. To augment the functionality of SMTP mail, a number of other Internet mail protocols were developed, including Post Office Protocol (POP) and Internet Message Access Protocol (IMAP), which enabled individual mailboxes to be assigned to users, and Multipurpose Internet Mail Extensions (MIME), which made it possible for text-based e-mail to contain binary information such as multimedia files and executables. SMTP itself was extended through SMTP Service Extensions and e-mail was made secure with such new technologies as Pretty Good Privacy (PGP) and Secure MIME (S/MIME).

Marketplace

For corporate messaging and collaboration, the market leader today is probably Microsoft Exchange 2000, a powerful platform that supports a host of features and can be deployed in a wide range of environments, from workgroups to enterprises to service providers. On the Internet, however, Sendmail is still the most popular program for forwarding SMTP mail.

Web-based e-mail allows users to access their personal mailboxes from anywhere on the Internet using a PC with a Web browser and a modem. Microsoft Exchange

2000 Server includes a feature called Outlook Web Access (OWA) that supports this kind of e-mail, as do Lotus iNotes R5, Novell GroupWise 5.5e, Imail Server from Ipswitch, and InScribe Internet Messaging Server Web Mail from Critical Path.

E

In the wireless messaging arena, a major player is Research In Motion (RIM) with its BlackBerry messaging system. The BlackBerry server application works with Microsoft Exchange or Lotus Notes mail servers and allows messages to be relayed to BlackBerry handheld devices. This allows mobile professionals such as IT (information technology) administrators, to be alerted when systems go down, and it is a more effective way of communicating than using simple pagers. BlackBerry is also a very secure messaging platform because it uses Triple Data Encryption Standard (Triple DES) for encrypting all transmissions.

Service providers, too, now offer various commercial e-mail services to businesses. For businesses that need to send out mass mailings and do not want to overwhelm their mail servers with these duties, companies such as BoldFish offer server software that simplifies the creation and transmission of large volumes of e-mail. Businesses can also outsource this activity to service providers.

Issues

The greatest obstacle to wider use of e-mail in business has been security. Traditionally, SMTP mail has been transmitted in clear text across the Internet, a notoriously unsafe place for such an action to be performed. The slow evolution toward universally trusted public key infrastructure (PKI) systems has hindered the widespread deployment of encrypted messaging and has led to other solutions such as PGP being adopted by some businesses in the meantime. Another solution called Privacy Enhanced Mail (PEM) was developed by the Internet Engineering Task Force (IETF) and is commercially offered by vendors such as RSA Data Security and Trusted Information Systems.

Besides the encryption issue, the last few years have seen the proliferation of what many thought could never occur: e-mail viruses. Some of these viruses have wreaked terrific havoc on corporate and commercial

messaging systems around the world. The first such instance was the Internet worm developed by Robert Morris in 1988, which took advantage of a weakness in Sendmail to bring down 6,000 SMTP mail servers around the globe in only 24 hours. More recent examples include the Melissa and LoveLetter viruses, which exploited enhanced collaboration features of Microsoft Outlook to crash mail servers at major Internet service providers (ISPs) and large corporations.

The growing trend toward Hypertext Markup Language (HTML) mail instead of plaintext messaging has also had its associated issues. For example, some marketing companies now send out their HTML messages with a tiny 1-pixel scripted image called a bug in them. The result is that when a user opens the message to read it in his mail program, information such as his Internet Protocol (IP) address and Web site visiting habits is collected from his machine and transmitted to the company. Some companies deal with such issues by simply disabling HTML mail altogether or preventing scripts from running on mail clients, but this seriously hinders the collaborative power of modern mail applications.

Prospects

E-mail continues to gain ground in the business world through such innovative technologies as Web-based messaging, which allows a user to access his personal mailbox from any Internet-enabled PC that has a Web browser on it, and wireless messaging, the “next big thing,” is starting to make big inroads in the enterprise through BlackBerry and Personal Digital Assistants (PDAs) Palm and PocketPC.

On the other hand, the next big thing may be the legal issues associated with the growing mountain of old e-mail residing on mail servers in back rooms of corporate networks. In regulated industries such as banking and securities trading, the law requires that all documents relating to business activity be retained for a number of years. Companies often archive old mail in user folders to file servers, but this makes it difficult to search for specific messages when required. In several instances, companies that were sued have been forced to settle because it was simply not cost-feasible for

them to search through hundreds of millions of old e-mail messages for documentation that could have won their case. It is important for companies to develop digital records management policies that articulate how old e-mail should be handled and to enforce these policies to limit their legal liability when challenged in court.

Even from a business point of view, having so much critical information stored in nonrelational database management system (RDBMS) systems such as mail servers means that executives and management sometimes lack the information necessary to make truly informed decisions. The emergence of Enterprise Knowledge Portals (EKPs) is one bright spot here, as these systems are designed in part to help tap the unrealized potential of business information stored in old e-mail.

e-mail address

Any address that ensures that an e-mail message reaches its intended recipient.

Overview

An e-mail address must contain sufficient information so that the message can be routed to its specific recipient. There are various kinds of e-mail address formats depending on the e-mail system in use. Address formats typically include at least two parts:

- **User portion:** This indicates the name or alias of the user to whom the mail is directed.
- **Routing portion:** This indicates the information needed to route the message to the particular mail system where the user’s mailbox resides.

The following table shows some examples of e-mail address formats.

E-Mail Address Formats

Type of Address	Example
SMTP (Internet)	JeffS@Northwind.Microsoft.com
Microsoft Mail	Northwind/MICROSOFT/JEFFS
Lotus cc:Mail	JeffS at Northwind
X.400	C=US;a=SPRINT;p=Microsoft;o=Northwind;s=JeffS

embedded system

Any type of small-footprint specialized computer system used in industrial, commercial, and consumer applications.

Overview

An embedded system is essentially a way of making ordinary industrial and consumer devices “smart” by embedding computer technology in them. An embedded system typically consists of a single microprocessor, a small amount of memory, a specialized operating system, and applications. These applications are used to control and manage certain functions of the device that contains the embedded system. Typical uses for embedded systems are control and monitoring of industrial machinery and automated management of plant and assembly line operations.

Embedded systems typically have limited processing power and task-specific applications that are used to control and manage larger systems. They may be responsive to environmental or user-controlled conditions and may operate alone or be networked to other systems by wireline or wireless networks, including the Internet.

Examples of embedded systems abound, including

- Industrial sensors and control equipment
- Automobile antilock brake systems
- Automobile Global Positioning Systems (GPSs)
- DVD and VCR players
- Digital cameras
- Microwave ovens

Some analysts estimate there are over 5 billion embedded systems in operation today in industrial, commercial, and consumer devices.

Marketplace

In the 1980s and 1990s, most embedded systems were variants on the 8086 and 8088 processors and used DOS as their operating system platform. In recent years the market has opened up, and a number of vendors are competing in the embedded operating systems marketplace. Big players include

- Microsoft Corporation, with its Windows CE and Embedded NT operating systems platforms. Microsoft's embedded operating systems have the advantages of having mature integrated development environments (IDEs) that allow developers to quickly create and deploy applications for embedded systems, and support Transmission Control Protocol/Internet Protocol (TCP/IP) networking, Internet, and wireless networking application programming interfaces (APIs) for building distributed networks of smart devices.
- Sun Microsystems, with its Java 2 Micro Edition (J2ME). J2ME exploits the ease of development of the Java platform and has a moderate memory footprint (128 kilobytes [kB] or higher). Third-party vendor Metrowerks has an IDE for J2ME called CodeWarrior that allows embedded J2ME applications to be developed rapidly and easily. Because of the sandbox implementation of the Java VM, however, J2ME is considered by some analysts to be unsuitable for time-sensitive deterministic embedded systems such as microprocessor control systems for spacecraft or automobiles.
- Red Hat Linux, with its Linux for Embedded Developers, offers the advantages of Linux's stability and small-footprint operation (32 KB or more).
- Wind River Systems, whose VxWorks embedded operating system has been used in devices as diverse as digital cameras, Hewlett-Packard printers, and the Mars Lander space vehicle built for the National Aeronautics and Space Administration (NASA).

Prospects

An impetus has been given to the embedded systems market in recent times through the widespread availability of the Internet. Most analysts expect that the greatest growth of embedded systems in the next few years will be in the area of small Internet appliances such as Web-enabled Personal Digital Assistants (PDAs) and cell phones. The continuing advancements in processor technology that have led to continually more powerful chips for continually lower prices have also provided impetus to the growth of the embedded sector.

Emergency Management Services (EMS)

A feature of the Microsoft Windows .NET Server family that allows servers to run in headless operation.

Overview

Traditionally, UNIX enterprise systems have been configurable for headless operation—that is, running servers without a keyboard, mouse, or video card. Such headless servers are typically used for greater security and are run behind closed doors. Administrators manage these systems by using Telnet to connect to them over the network and issue administrative commands.

Windows .NET Server supports headless operation through its Emergency Management Services (EMS) feature. EMS allows a Windows .NET server to be run in headless mode and managed using a Telnet-based administration console. All management instructions are sent to the headless server using text-based commands.

Implementation

To implement a headless server, you must first enable EMS on the server, either through selecting this option during setup or by configuring the boot loader file afterward. A null modem is then used to connect the headless system through its serial port to VT100 terminal emulation software on a client machine. If the hardware

supports it, the VT100 client can also manage the headless server through the universal serial bus (USB) port or over an Ethernet network using an RJ-45 jack.

Notes

To run Windows .NET Server in headless mode, the system's basic input/output system (BIOS) must allow operation without a video card, keyboard, or mouse.

emergency repair disk (ERD)

A Microsoft Windows 2000 recovery tool for repairing missing or corrupt files and restoring the registry.

Overview

In Windows NT, the emergency repair disk (ERD) was a valuable recovery tool for restoring the registry or replacing boot files on a corrupted system. The Windows NT ERD contained compressed versions of registry hive, default user profile, setup.log, and other system configuration files, and it could be created from the command line using the Rdisk command.

In Windows 2000, the ERD is a little different. Instead of containing registry hives, it contains only boot files and some pointers to operating system files. When a Windows 2000 system is first installed, the registry hives are backed up to \Winnt\repair directory. Also, the ERD is created by selecting an option in the Windows 2000 Backup tool. When the Backup tool is used to back up the registry, this backup is placed in \Winnt\repair\regback.

You can use the ERD to restore a corrupted master boot record (MBR), restore missing or corrupted boot files such as Ntldr, or restore the registry from backup. However, when ERD is used to restore the registry, it does so from \Winnt\repair instead of \Winnt\repair\regback, using the pristine form of the registry that is backed during the initial installation. For more fine-grained control of restoring the registry, use the new Recovery Console tool of Windows 2000 instead of the ERD.

Having a current copy of the ERD for each server on your network is a critical part of preparing for disaster

recovery. Always create a new ERD after installing new services or software or upgrading hardware or device drivers on a system.

Uses

To perform a system recovery on a machine running Windows 2000, try booting to Safe Mode first by pressing the F8 function key during startup. If this fails or if the system cannot be repaired, boot the system using the four boot floppies, select the Repair option by pressing the R key when prompted, and then either use the ERD to attempt a repair or press C to open the Recovery Console. The Recovery Console is a powerful command-line interface to the operating system designed for use only by advanced administrators.

Notes

If you cannot find your four Windows 2000 boot floppies, insert the Windows 2000 compact disc and a blank floppy into any machine running MS-DOS or Windows, click Start, select Run, and enter the following path into the Run box:

```
<cdrom_drive>\bootdisk\makeboot a:
```

In Windows XP and Windows .NET Server, ERD is being replaced by a feature called Automated System Recovery (ASR).

See Also: *Automatic System Recovery (ASR)*

emergency startup disk

A floppy disk created during the setup process for Microsoft Windows 98 and Windows Millennium Edition (Me) that can be used to troubleshoot boot problems.

Overview

The emergency startup disk contains files necessary to load a command-line version of Windows, plus other useful system-recovery utilities, including a real-mode registry editor. When you insert an emergency startup disk into your computer and reboot, the computer starts from the disk instead of from the hard drive.

Having a current copy of the emergency startup disk for each machine running Windows 98 or Windows Me on your network helps with disaster recovery if these machines fail to boot properly. You should create a new

emergency startup disk whenever you make a configuration change to a machine running Windows—for example, when you install new hardware or update device drivers.

Stands for Emergency Management Services, a feature of the Windows .NET Server family that allows a server to run in headless operation.

See: Emergency Management Services (EMS)

emulation

Any process by which one device mimics the functions of another device.

Overview

In computer networks, emulation usually refers to protocol conversion, a process by which a device that understands one protocol can speak with a device that understands a different, incompatible protocol. The environment in which emulation is chiefly used is mainframe computing, where asynchronous terminal emulators are used to emulate and replace more expensive synchronous terminals. For example, a PC with a modem and VT100 terminal emulation software can replace a synchronous VT100 terminal, eliminating the need for a dedicated serial connection between the mainframe and the terminal.

Common types of mainframe terminal emulators include

- **3270:** The 3270 synchronous protocol is used by IBM mainframe hosts that use the Systems Network Architecture (SNA).

- **5250:** The 5250 synchronous protocol is used in the IBM S-series mainframe environment and in AS/400 midframe environments.

Encapsulating Security Payload (ESP)

A protocol in the IPsec suite of protocols that handles encryption.

Overview

IPsec is actually a suite of protocols that consists of two main protocols:

- **Authentication Header (AH):** This protocol ensures that IPsec packets have not been altered during transmission and to verify the sender's identity. AH is included in IPsec to provide authenticity.
- **Encapsulating Security Payload (ESP):** This protocol ensures that IPsec packets cannot be read except by their intended recipients. ESP is included in IPsec to provide privacy.

ESP is generally used in conjunction with AH to provide maximum security and integrity for IPsec transmissions. However, either ESP or AH can be used alone if sufficient for the intended purposes.

By default, ESP uses the symmetric encryption algorithm Data Encryption Standard (DES) to encrypt the payload of an IPsec packet. ESP can also be configured to use Triple DES, depending upon encryption export restrictions of the business involved.

encapsulation

Generally, the process of enclosing one type of data packet using another type of data packet.

Overview

Encapsulation occurs when a lower-layer protocol receives data from a higher-layer protocol and then places the data into the data portion of its packet format. Encapsulation at the lowest levels of the Open Systems

Interconnection (OSI) reference model is usually referred to as framing. Examples of different types of encapsulation include

- An Ethernet frame that encapsulates an Internet Protocol (IP) packet, which itself encapsulates a Transmission Control Protocol (TCP) packet, which then encapsulates the actual data being transmitted over the network
- An Ethernet frame encapsulated in an Asynchronous Transfer Mode (ATM) frame for transmission over an ATM backbone

The data-link layer (Layer 2) of the OSI networking model is responsible for encapsulating or framing data for transmission over the physical medium. In local area network (LAN) technologies, this is usually Carrier Sense Multiple Access with Collision Detection (CSMA/CD) for Ethernet networks. For wide area network (WAN) technologies, the data-link protocols used depend on whether the communications are point-to-point or multipoint:

- For point-to-point communications, possible WAN data-link protocols include Point-to-Point Protocol (PPP) and High-level Data Link Control (HDLC) protocol.
- For multipoint communications, possible WAN data-link protocols include frame relay, ATM, Switched Multimegabit Data Services (SMDS), and X.25.

Encrypting File System (EFS)

A feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that allows files stored on NTFS file system (NTFS) volumes to be secured through encryption.

Overview

Encrypting File System (EFS) is designed to protect data on NTFS volumes from local access by unauthorized user EFS which does not work on FAT or FAT32 volumes encrypts information in files at the bit level so that if a hard drive is stolen from a user's system and

placed in another system, the information on the drive will be unreadable. In this way, EFS ensures the privacy of a user's information stored on disk and finds particular application with systems vulnerable to theft, such as laptop computers.

EFS is integrated in the NTFS used by Windows 2000, Windows XP, and Windows .NET Server; it is not available for older forms of NTFS, such as the one used in Windows NT 4. EFS operates transparently from the point of view of users: files are automatically encrypted when they are created or moved to encrypted folders and are automatically decrypted when the user needs to access the information stored within them.

EFS also includes a Data Recovery System that employs a trusted recovery agent (usually the Administrator account) that can decrypt any user's encrypted files in an emergency.

The following EFS features have been added to Windows XP Professional and Windows .NET Server editions:

- Additional users can be authorized to access encrypted files.
- Offline files can now be encrypted.
- Data recovery agents are recommended options.
- The Triple-DES encryption algorithm can be used to replace DESX.
- A password reset disk can be used to safely reset a user's password.
- Encrypted files can be stored in Web folders.

Implementation

EFS employs a combination of private and public key cryptography schemes. When EFS receives a request to encrypt a file, a secret (private) key is automatically generated in the form of a random number string. This secret key is called the File Encryption Key (FEK) and is generated using a modified version of the Data Encryption Standard (DES). The FEK itself is secured by encrypting it using the user's private key—a public/private key pair is automatically generated for each user and stored in Active Directory directory service. The encrypted FEK is stored on disk with the user's encrypted files.

The advantage of using this combination of two encryption schemes is that the faster symmetric encryption scheme is used for actual encryption and decryption of file data and the slower public key scheme is used only to protect the user's own private key from theft and misuse. Although EFS employs public key encryption, it does not require a certificate authority (CA) to issue public/private key pairs. Instead, EFS automatically generates these key pairs for individual users and for trusted recovery agents.

Notes

If you are working with applications that create temporary files, you might want to enable encryption at the folder level instead of the file level to guard against unauthorized access to your temporary files. With folder-level encryption, all files in the folder are encrypted.

encryption

The process of rendering information unreadable to all but the intended recipients, who have the ability to decrypt it.

Overview

Cryptography is the science of creating workable procedures for encrypting and decrypting messages. Encrypting messages and transmissions ensures their

- **Privacy:** No one can read an encrypted message other than its intended recipients.
- **Integrity:** An encrypted messages that is intercepted in transit and modified generally becomes garbage when received by its intended recipient—a simple test of whether the message has been tampered with.
- **Authenticity:** A good encryption scheme will help you verify that the message was indeed sent by the person it says it is from by authenticating the identity of the sender.

Cryptography's goal is to ensure that an encrypted message intercepted by a distrusted user cannot be decrypted in a feasible amount of time. Encryption is synonymous with cryptography and has been the basis

of all secure communications since ancient times. With the rapid growth in recent years of the Internet as the de facto medium for businesses and consumers to exchange information, encryption has taken on new importance resulting in an explosion of cryptographic technologies and standards has resulted.

Uses

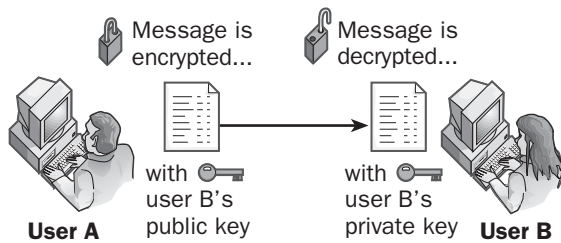

Symmetric key encryption is widely used for securing digital transmission of information. For example, the DES encryption scheme used by the U.S. government since 1974 is a symmetric key encryption algorithm, as is its recent successor, the Advanced Encryption Standard (AES). Symmetric key encryption is also employed in the Windows NT LAN Manager (NTLM) authentication scheme of Microsoft Windows NT and in Kerberos, the default authentication scheme of Microsoft Windows 2000, Windows XP, and Windows .NET Server.

Asymmetric or public key encryption, on the other hand, is widely used on the Internet in the form of the SSL protocol discussed previously. Public key encryption was developed by Whitefield Diffie and Martin Hellman in 1976, and it was made popular by Phil Zimmerman with his Pretty Good Privacy (PGP) encryption scheme for e-mail messaging, which was first released in 1991.

Asymmetric encryption is much slower than symmetric encryption, so many encryption technologies use a combination of the two. In SSL, for example, asymmetric encryption is used during SSL session initialization to securely exchange a secret key between users so that the remaining encryption performed during the session is done using the much faster symmetric encryption scheme.

Implementation

The basic element that makes possible both encryption and decryption is the key. A key is typically a numeric value that is employed in a mathematical procedure called an encryption algorithm to convert ordinary text (plaintext) into encrypted text (ciphertext) and vice versa (encryption algorithms are discussed separately in the corresponding article in this chapter). The number of keys used and the details of how they are employed distinguishes two basic types of encryption, namely symmetric and asymmetric (public) key encryption.

Encryption. *The public key encryption method.*

Symmetric key encryption uses a secret key known only to the sender and the recipient of the message (and perhaps to others whom they trust). The secret key is used to encrypt the message when it is sent and to decrypt it when it is received. The actual encryption process involves mathematically combining (hashing or transforming) the message and the key in some complex fashion that is virtually impossible to undo unless the recipient also has the key. Symmetric key encryption is very secure, but suffers from one problem—if you want to send a message to someone who does not have your key, you must also find a way to securely transmit a copy of the key. This difficulty makes symmetric key encryption generally unworkable for electronic communication over a network or telecommunications service, except where only the original sender and recipient will need the key. For example, symmetric key encryption works in cellular phone communication when only the subscriber and the service provider need a copy of the user's key. Symmetric key encryption is the oldest form of encryption, dating from at least Roman times.

Asymmetric or public key encryption is a newer method that is becoming widely used in many computer networking and telecommunications systems. For example, public key encryption is employed by the Secure Sockets Layer (SSL) protocol used for transmitting sensitive information such as credit card numbers over the Internet. SSL establishes a secure communications session over the Internet by using public key encryption, which provides every participating user with a public key and a private key. Users are the only ones who know their private keys, whereas their public

keys are generally available to anyone who wants them. Remember that if a message is encrypted with a user's public key, it can be decrypted only with the same user's private key, and vice versa.

For example, in public key encryption, if user A wanted to send an encrypted message to user B, it would typically work like this:

- 1 User A requests user B's public key or obtains this key from a certificate authority (CA) that both users trust.
- 2 User A encrypts his message using user B's public key and sends the encrypted message to user B.
- 3 User B receives the encrypted message from user A and decrypts it with user B's private key.

The preceding approach outlines the steps used for encrypting and decrypting the actual message being transmitted during a secure communication session. A different approach, called a digital signature, is used to confirm the sender's authenticity and the message's integrity. Digital signatures are encrypted in a reverse fashion to the message itself. Specifically, if user A wants to send his digital signature to user B, then

- 1 User A creates a hash of his message using a hashing algorithm. This hash forms the basis of the digital signature, which user A then encrypts using his own private key.
- 2 User A appends the encrypted digital signature and his own public key to the message, which is then encrypted using user B's public key.
- 3 User B receives the message and attachments, decrypts its contents using her own private key, and uses user A's public key to decrypt the digital signature that he attached to the message. User B then generates a hash of the received message and compares this to the digital signature that user A sent. If the two are identical, it is unlikely that the message has been tampered with in transit.

Issues

Export of encryption technology is controlled by U.S. law. Certain encryption schemes can be exported only to trusted nations and might require a government review before such export is allowed.

encryption algorithm

A mathematical procedure for encrypting data using a key.

Overview

Encryption algorithms form the basis by which encryption can take place and are fundamental to cryptography. Encryption algorithms generally use some kind of mathematical key (chosen from a large set of available keys) to transform plaintext (the data being encrypted) into ciphertext (the resulting encrypted data). An encryption algorithm must be reversible so that the recipient can use another mathematical key to decrypt the data. A good encryption algorithm should be difficult to decrypt if you do not know the decrypting key, and the only method that should be possible to force decryption should be the brute force method of simply trying every possible decryption key (in other words, there must be no shortcuts or back doors for decryption). If an encryption algorithm is really good, it would take massively parallel computers centuries, or even eons, of intense processing, trying all possible keys, to decrypt a single message if they do not know the specific decryption key.

Implementation

Encryption algorithms typically perform their encryption process on multibyte segments of data instead of on one byte at a time. Such an algorithm is known as a block cipher because it encrypts data one block at a time. For example, the Data Encryption Standard (DES) algorithm, a 56-bit key algorithm used for many years by the U.S. government, encrypts data 64 bytes at a time.

Encryption algorithms employ mathematical procedures called hash functions, which are repeatedly

applied to plaintext to scramble it into ciphertext. The combination of a hash function and a key form the basis for the encryption process.

Examples

Encryption algorithms are of two basic types: symmetric and asymmetric.

Symmetric algorithms employ the same key, called a secret key, for both encryption and decryption of a message. This process is also known as symmetric or secret key cryptography. Examples of symmetric algorithms include

- **DES:** This uses a 56-bit key and was the U.S. government standard for encryption until 2001, when it was replaced by the Advanced Encryption Standard (AES). DES is no longer considered secure and was first cracked in 1997.
- **AES:** This can use keys up to 256 bits in length, and it has replaced DES as the official U.S. government encryption standard.

Asymmetric algorithms employ a different key for encrypting and decrypting data. The two keys are mathematically related and are called a key pair, with the private key used for encrypting the message and the public key used for decrypting it. Examples of asymmetric algorithms include

- **Diffie-Hellman:** Developed by Whitefield Diffie and Martin Hellman in 1976, this is the original public key encryption algorithm and is used in the Secure Sockets Layer (SSL) protocol on the Internet for securely exchanging secret keys between remote systems.
- **Rivest-Shamir-Adelman (RSA):** Developed in 1977 by the Ron Rivest, Adi Shamir, and Leonard Adelman, this algorithm can be used both for encryption and secure authentication. It is used in SSL, Transport Layer Security (TLS), and IPsec communications in virtual private networks (VPNs) and over the Internet.

End-User License Agreement (EULA)

A type of contract between a computer software publisher and the purchaser of the software that outlines the various rights granted to the purchaser for legal use of the software.

Overview

The End-User License Agreement (EULA) for a software product is usually found on a separate piece of paper accompanying the product, inside the front cover of the user manual, or onscreen prior to installing the software. You should read and become familiar with the terms of your EULA for the software you purchase. Failure to follow the terms of the EULA might expose you or your company to prosecution for software piracy.

You can access the EULA for Microsoft Windows Millennium Edition (Me) by opening the text file License.txt. It is located in the \Windows folder. In Windows 2000, Windows XP, and Windows .NET Server, the file is called eula.txt and is located in the \System32 folder.

enhanced Category 5 (Cat5e) cabling

Also known simply as Cat5e, a recently ratified standard for structured local area network (LAN) wiring.

Overview

Enhanced Category 5 (Cat5e) cabling is the only ratified cabling standard that is capable of supporting transmission speeds faster than 100 megabits per second (Mbps), although Category 6 (Cat6) and Category 7 (Cat7) specifications have been proposed. Supporting frequencies up to 350 megahertz (MHz) or higher, Cat5e cabling is typically four-pair solid conductor 24-gauge unshielded twisted-pair (UTP) cabling that has a low capacitance in the range of 13 to 14 pF/foot, as compared with regular Category 5 (Cat5) cabling that has a capacitance of around 17 pF/foot. The impedance of Cat5e cabling is 100 ohms, the same as for regular Cat5 cable.

Other specifications of Cat5e include

- Attenuation less than 22 decibels (dB) at 100 MHz (same as Cat5)
- Near-end crosstalk (NEXT) less than 35.3 dB (3 dB higher than Cat5)
- Power-sum NEXT (PS-NEXT) less than 32.3 dB (unspecified for Cat5)
- Return loss less than 20.1 dB (unspecified for Cat5)

Uses

The electrical characteristics of Cat5e cabling make it the recommended type of cabling for most new installations of structured wiring, especially companies planning an eventual migration from Fast Ethernet to 1000BaseTX Gigabit Ethernet (GbE). Cat5e cabling can be used for Ethernet, Integrated Services Digital Network (ISDN) wiring, and 155-Mbps Asynchronous Transfer Mode (ATM) networks.

If you plan to use Cat5e cabling in your network, you should ensure that all your other wiring components match these specifications. This means purchasing and installing enhanced Cat5 patch panels, wall plates, and other components. Also, be sure to strictly follow wiring guidelines because improper installation of Cat5e cabling will result in loss of potential bandwidth. The real key to operating a successful high-speed UTP wiring system is careful installation.

Enhanced Data Rates for Global Evolution (EDGE)

A third-generation (3G) upgrade for the 2.5G General Packet Radio Service (GPRS).

Overview

Enhanced Data Rates for Global Evolution (EDGE) was designed as a way of easily upgrading certain second-generation (2G) cellular systems to 3G systems with little additional cost. EDGE can be used to upgrade both Time-Division Multiple Access (TDMA) systems such as AT&T Wireless and Global System for Mobile Communications (GSM), which are also based on TDMA

technologies. EDGE cannot be used to upgrade Code-Division Multiple Access (CDMA) systems. The official 3G upgrade for CDMA systems is instead the International Telecommunication Union's (ITU) Wideband CDMA (W-CDMA) standard. EDGE is designed to provide mobile users with wireless roaming data services of up to 400 kilobits per second (Kbps).

EDGE comes in two flavors:

- **Enhanced Circuit-Switched Data (ECSD):** This is EDGE technology applied to circuit-switched GSM systems, which provide direct connection to the Public Switched Telephone Network (PSTN) backbone.
- **Enhanced GPRS (EGPRS):** This is EDGE technology applied to packet-switched General Packet Radio Services (GPRS) systems, which routes Internet Protocol (IP) packets over the Internet.

Implementation

EDGE works by modifying the physical layer of GSM and GPRS to increase data transmission rates threefold. This is accomplished by replacing the Gaussian Minimum Shift Keying (GMSK) encoding mechanism of GSM and GPRS, which only allows one bit of information to be encoded per symbol, to 8-bit Phase Shift Keying (8-PSK), which encodes 3 bits per symbol. The result is that the theoretical transmission speed of GPRS is raised from 171 Kbps to 513 Kbps, with similar effect for GSM (these theoretical speeds are not realized in practice due to bandwidth being used for error correction).

Above the physical layer, EDGE uses the same technologies as GSM and GPRS. Existing GSM and GPRS cellular networks are easy to upgrade to EDGE, because the same equipment can be used for both the older 2G services and the newer 3G EDGE (though some hardware and software upgrades are required). In addition, costs remain low because no additional frequency licenses are required for EDGE. Although the 400-Kbps data rates offered by EDGE fall short of the envisioned 2-megabit-per-second (Mbps) speeds for 3G cellular systems, EDGE has been ratified as an official 3G system by the ITU in its IMT-2000 specifications.

Marketplace

In North America, EDGE will soon be deployed by AT&T, the major Time Division Multiple Access (TDMA) cellular provider. This will be done in stages, first by upgrading the TDMA system to GSM together with an overlay of GPRS to support data rates of 144 Kbps. The GSM/GPRS system will then be upgraded to EDGE to provide data rates of 384 Kbps. Further 3G upgrades are likely down the road, pushing speeds to 2 Mbps.

Prospects

Although EDGE is an official standard, it is not likely to be supported in many areas outside North America because most other countries having 2G TDMA systems are likely to upgrade them to W-CDMA instead, which is incompatible with EDGE.

Enhanced Interior Gateway Routing Protocol (EIGRP)

A popular interior routing protocol developed by Cisco Systems.

Overview

Enhanced Interior Gateway Routing Protocol (EIGRP) is a proprietary interior routing protocol developed by Cisco to overcome certain weaknesses of IGRP (Interior Gateway Routing Protocol), an earlier proprietary routing protocol also developed by Cisco. EIGRP is a reliable, efficient dynamic routing protocol that converges quickly and avoids routing loops. EIGRP is intended for classless routing within an autonomous system (AS) and provides a way for routers within an AS to exchange routing table information with each other.

EIGRP is a hybrid protocol that employs features of both distance vector and link state routing protocols. EIGRP is similar to IGRP in several ways:

- EIGRP is a classless interior routing protocol used inside an autonomous system.
- EIGRP uses a distance vector algorithm for calculating route metrics based on link characteristics instead of hops.

- Metrics can be based on values of bandwidth, route latency, reliability, and load.

But EIGRP also differs from IGRP in many ways, and most of these differences involve the incorporation of features common to link state routing protocols. For example:

- EIGRP includes a mechanism for automatically discovering neighboring routers using HELLO packets and downloading necessary routing information from these neighbors.
- Instead of using periodic broadcasts of entire routing tables, which consumes valuable network bandwidth, EIGRP sends out only incremental updates for routing tables and only when a change in the tables requires such updates.
- Routing table information is contained within a topology database similar to that used by link state routing protocols. Only information about adjacent routers is kept in the database, not the routing table for the entire network. This helps keep the topology database small and efficient for fast routing and helps an EIGRP router to recover quickly after a failure.

Other features of EIGRP include

- **Diffusing Update Algorithm (DUAL):** This complex routing algorithm that is similar to Dijkstra's algorithm provides fast convergence and avoids routing loops.
- **Reliable Transport Protocol (RTP):** This protocol guarantees delivery of EIGRP packets to neighboring routers.
- **Protocol-dependent modules:** This feature allows an EIGRP router to support multiple network protocols including Internet Protocol (IP), Internetwork Packet Exchange (IPX), and AppleTalk.
- **MD5 authentication:** Each EIGRP packet contains an MD5 checksum to secure routing communications from outside monitoring.

Notes

Although EIGRP and IGRP share some characteristics and can work together, they are essentially different

protocols (by contrast, RIPv2 is simply Routing Information Protocol [RIP] with a few added features).

EIGRP can also work seamlessly with IGRP to allow routing information to be shared across boundaries of autonomous systems, which simplifies the setup and configuration of EIGRP routers considerably.

enterprise

A large, geographically distributed company with a high number of users.

Overview

In a computer networking context, an enterprise-level network of computers refers to the network belonging to an enterprise; that is, a network that typically consists of thousands of computers distributed across several geographically remote locations and connected by wide area network (WAN) links.

Enterprise-level networks generally use Transmission Control Protocol/Internet Protocol (TCP/IP) and are divided into a number of smaller networks called subnets, which are linked by routers. Enterprise-level networks are often heterogeneous networks consisting of different protocols and operating systems such as Microsoft Windows NT, Windows 2000, Windows XP, Windows .NET Server, Novell NetWare, and varieties of UNIX, all interoperating to various degrees. Enterprise-level networks can include legacy mainframe and minicomputer systems as well.

This mixture of systems and protocols can make it challenging to administer and manage an enterprise-level network and offers a strong argument for upgrading legacy systems to newer, standardized ones. Companies can save considerable costs in the long run by upgrading their networks to secure, reliable, scalable network operating systems such as Windows NT, Windows 2000, Windows XP, or Windows .NET Server. The initial cost of upgrades and training are quickly recouped through lower maintenance and administration costs, the result of migrating an

enterprise's heterogeneous combination of systems and protocols to a homogeneous network consisting of computers running Windows NT, Windows 2000, Windows XP, or Windows .NET Server and running TCP/IP.

Enterprise Admins

A built-in group for the Microsoft Windows 2000 and Windows .NET Server operating system platforms.

Overview

Enterprise Admins is one of four global groups that Windows 2000 and Windows .NET Server create by default to help administrators organize users in their network. The other three groups are Domain Users, Domain Guests, and Domain Admins.

Although Domain Admins are users who can perform administrative tasks on any computer belonging to the domain, the Enterprise Admins group is intended to have an even larger scope. Enterprise Admins must be able to perform administrative tasks on any computer in the enterprise.

A Windows 2000– or Windows .NET Server–based enterprise can consist of a number of domains interconnected in a domain tree, or even several domain trees connected into a domain forest. Enterprise Admins can administer the entire network for the enterprise.

Just as with the Domain Admins group, the Enterprise Admins group has one initial member: the Administrator user account that belongs to the domain. The Enterprise Admins group exists only in the root domain of the forest.

Enterprise Information Portal (EIP)

A business software system used to provide a single point of access to information stored in different corporate databases.

Overview

Enterprise Information Portals (EIPs) are an evolution of corporate intranets that apply portal technologies to help

manage the flood of information that fuels business. Although the intranet revolutionized the way businesses handled information by providing a standard interface (the Web browser) for accessing such information, portals provide other tools such as user profiles, personalization services, workgroup and collaboration tools, automatic indexing, and push/pull information delivery that help manage large amounts of information residing in the diverse data sources of a typical enterprise.

EIPs are simply a wedding of these two technologies, turning corporate intranets into collaborative tools that deliver personalized business information to users as they need it. EIPs generally focus on managing structured information found in databases of two common types of business applications: enterprise resource planning (ERP) and customer relationship management (CRM) applications. EIPs excel in helping users identify, analyze, and present useful information mined from diverse databases used by businesses, and are in many ways simply an extension of data warehousing (DW) and data mining (DM) technologies with an additional emphasis on integrated content management (CM) technologies. EIPs generally excel in bringing together data found in structured data sources such as structured query language (SQL)– and open database connectivity (ODBC)–compliant databases. A further evolution of these systems called Enterprise Knowledge Portals (EKPs) can also mine unstructured sources such as e-mail message repositories and document management systems.

Marketplace

Many new players have appeared since the EIP market exploded in 1999. Some of the early pioneers that have gained significant market share with their packaged EIP offerings include HummingBird International, Epicentric, and Plumtree Software. Some examples of popular EIP offerings in the marketplace include Brio.Portal from Brio Technology, Corporate Portal from Plumtree, DataChannel server from DataChannel, Freedom from InfoImage, iPlanet Portal server from Sun-Netscape Alliance, and many others.

Major operating system and business applications vendors such as IBM, Oracle Corporation, Microsoft

Corporation, and Sun Microsystems also offer suites of business applications that can be used to help build EIP solutions for corporate customers. Some EIP applications are more focused on providing corporate users with work-group tools for collaborative use, and others focus more on enabling decision-makers in a company to access the information they need to map their company's future.

Prospects

The EIP market, which started in 1998, has grown to a multibillion-dollar industry and is expected to rival the traditional ERP and CRM markets in the next few years in scope and deployment.

Enterprise Java Beans (EJB)

A Java-based technology from Sun Microsystems for building e-commerce systems.

Overview

Enterprise Java Beans (EJB) is a set of Java specifications that can be used for building Web-based distributed transactional applications typical of e-commerce and e-business solutions. EJB is a core component of Java 2 Enterprise Edition (J2EE) and works with Java Server Pages (JSP) technologies to provide tools for developers to meet the needs of businesses in today's Internet economy. EJB is particularly popular in the UNIX environment as an alternative to Common Gateway Interface (CGI) solutions based on PERL and C/C++, but EJB applications can run on any Java-supporting platform, including Linux, Solaris, AIX, Windows NT and Windows 2000.

EJB was developed under the umbrella of the Java Community Process, and its current version 1.1 is being revised toward version 2.

Implementation

EJB is implemented as an object-oriented component programming model based on the Java programming language. As a result, EJB is a platform-independent and vendor-neutral solution for building transactional applications. EJB supports both stateful and stateless transactions through its different types of session beans. It can

be used to build scalable, distributed applications that run on farms of application servers, and its component-based technology speeds and simplifies the development process to gain better time-to-market advantage.

EJB operates as a server-side component technology. It includes a number of services that make it easy for developers to write middleware supporting distributed transactional processing over the Internet. These services include database connectivity, support for distributed transactions, and security functions.

Marketplace

IBM and Inprise/Borland Corporation both offer EJB server platforms for building e-business solutions. Another company that is a popular player in this market is BEA Systems. The open-source movement is contributing its own EJB server platform, called jBoss, as well.

Enterprise Knowledge Portal (EKP)

A business software system that couples knowledge management tools with an Enterprise Information Portal (EIP) to provide a powerful way of handling the flood of information that characterizes large businesses today.

Overview

Information is at the center of today's business, but this information is typically stored in diverse places, such as:

- **Structured data sources:** This includes information in enterprise resource planning (ERP), customer relations management (CRM), and various structured query language (SQL) and open database connectivity (ODBC) databases scattered on servers throughout an enterprise.
- **Unstructured data sources:** This includes e-mail, scheduling, and journaling information stored on mail servers and groupware servers, document management systems that include file servers and document archive systems, and Web-based information repositories such as intranets, extranets, and public Web sites.

- **Legacy data sources:** This covers all forms of data stored on legacy systems such as IBM mainframe and AS/400 systems.

Enterprise Knowledge Portals (EKPs) are systems that gather all these sources of information and allow corporate users to locate, analyze, deliver, and present personalized information through a single point of access. Using the simple Web browser as the universal front end for these systems, users can pull useful information from these sources to help them make informed business decisions or have this information pushed out to them on a regular basis using automatic search engines that parse the data sources using intelligent criteria to determine what users might need. User profiles allow EKPs to personalize the information delivered to users to present what they need, when they need it, and how they need it.

Implementation

EKPs work by combining two technologies:

- **Enterprise Information Portals (EIPs):** These systems are essentially portals to corporate intranets and provide features such as user profiles, personalization services, single sign-on, customizable interface, automatic indexing, and push/pull delivery of information to basic Web-based intranet systems.
- **Knowledge Management (KM):** These tools enable useful information to be combined and mined from sources as diverse as SQL databases, Word documents, spreadsheets, slide-show presentations, text files, and e-mail repositories.

By combining these two kinds of tools, EKP allows information of every form within a company to be unlocked and made available for making informed business decisions.

Advantages and Disadvantages

Although an EKP's advantages are clear in that it provides a unified single point of access to a company's varied sources of business information, the disadvantages are also clear, in that EKP systems are costly to set up and complex to implement. In particular, building an EKP into a company's varied sources of data could

require months, or even years, to implement fully, with much of that time spent on custom development work. On the other hand, once these systems are fully implemented, they are easy to maintain and they bring significant long-term cost savings by enabling faster, more informed decision-making and improved communications among corporate users.

Marketplace

A number of companies are offering turnkey EKP solutions that can fit the needs of medium-sized companies without much development work. Portal-in-a-Box from Autonomy Corporation is one example of a turnkey EKP system that automatically classifies, links, and personalizes information and then delivers it to users as they need it.

Big players such as Lotus Development Corporation and OpenText Corporation also offer EKP systems that focus more on the collaborative aspect of business decision-making. And major business application vendors such as Microsoft Corporation, IBM, Sun Microsystems, and Oracle Corporation offer their own suites of applications that can be used to build EKP systems for large enterprises.

enterprise resource planning (ERP)

A term describing software systems for managing a broad scope of an enterprise's business functions.

Overview

Enterprise resource planning (ERP) includes tasks such as planning, purchasing, tracking orders, supplying customers, managing inventory, servicing customer requests, producing financial reports, and bookkeeping. ERP software is modular software designed to integrate these various business functions and simplify their management.

ERP software typically consists of an integrated suite of tools for performing standard line-of-business functions such as payroll, accounting, inventory management, and order entry. ERP software is used in transportation

and automotive businesses, industrial environments, and other large industrial settings. ERP software lets these businesses manage diverse business resources across the enterprise to plan more effectively for growth and expansion.

History

ERP has its roots in the software-controlled inventory control systems developed and used by large companies in the 1960s. These systems evolved in the 1970s to include scheduling features for automating procurement for assembly-line systems and were then called Material Requirement Planning (MRP) systems. During the 1980s, MRP systems continued to evolve to include distribution and shop floor control and management capabilities and became known as Manufacturing Resources Planning (MRP-II) systems. In the 1990s, these systems were further extended to include the full gamut of business functions, including project planning, engineering, finance, and human resources. The term *enterprise resource planning* emerged at this time to represent the wider scope of these large software systems.

Marketplace

The three big players in the traditional ERP marketplace are Oracle Corporation, PeopleSoft, and SAP. The biggest of these vendors is Germany's SAP AG, which has an estimated 35 percent share of the ERP market, mainly with its SAP R/3 suite of ERP applications. Another big player is Baan, which has both a traditional ERP offering and an initiative to integrate Extensible Markup Language (XML)-ERP platform through their Baan OpenWorld Integration Framework.

Traditional ERP systems are expensive and often take years to implement fully for large enterprises. In the last few years, a flood of new companies entered the marketplace offering applications that would provide Web-based front ends for traditional ERP software to Internet-enable this software for simplifying enterprise business management. One example of this is the Online Information System (OIS) from Impress Software, which uses the application programming interfaces (APIs) from the big three ERP software vendors to provide businesses access to their SAP R/3 manufacturing systems and other enterprise applications over the Internet.

OIS has support for both XML and electronic data interchange (EDI) information exchange, and it is available for diverse platforms, including Windows NT, UNIX, and Linux.

With the proliferation of third-party solutions, the big three have also moved recently to Internet-enable their traditional ERP offerings to make them more competitive. An example is mySAP from SAP AG, which integrates customer relations management (CRM) functions with ERP and provides a portal front end. Although previously most ERP deployments were performed by consulting companies, the Big Three have moved recently to offer their professional services.

Prospects

The most obvious trend in the ERP market is the continuing effort to fully Internet-enable ERP systems and processes. Although early attempts at this represented no more than embedding legacy client ERP interfaces within Web browsers, ERP systems continue to evolve to make their Web-based interface friendlier and easier to use.

ERP was more than a \$20-billion market in 2000 and is expected to grow over the next few years. A large portion of this represents planning, consulting, licensing, and maintenance fees for such systems. One recent development is Enterprise Information Portals (EIPs), which provide a new and innovative way of managing the flood of business data that traditional ERP applications expose. EIPs integrate the functions of ERP, CRM, and SCM (supply-chain management) systems into a single Web-based system. Many analysts believe that traditional ERP implementations are on their way out and more sophisticated and powerful EIP systems will grow rapidly, but because of the huge investment most large enterprises have put into ERP systems and the ongoing costs of maintaining them, ERP is likely to be with us for many years.

enterprise server

A designated server running Microsoft Windows NT, Windows 2000, or Windows .NET Server in an enterprise, which is used as a central repository for software

licensing information regarding Windows NT, Windows 2000, Windows .NET Server, and Microsoft BackOffice.

Overview

E In Windows NT networks an enterprise server is typically a primary domain controller (PDC), yet can also be a stand-alone server that is not part of any domain in the enterprise. All PDCs in the enterprise replicate their licensing information with the enterprise server, so the enterprise server contains a master database of this information. If there is only one domain in the enterprise, the PDC for that domain is the master licensing server. If there are several domains, each domain's PDC keeps track of licenses for that domain, and all PDCs then replicate their licensing information to the specifically designated enterprise server. Stand-alone member servers that are not part of any domain also must replicate their licensing information with the enterprise server.

They can be more than one enterprise server in an enterprise, but it is simplest to have only one because enterprise servers cannot replicate with each other.

environmental subsystems

Components of Microsoft Windows NT, Windows 2000, Windows XP, and Windows .NET Server that support the running of applications from different operating system architectures.

Overview

Environmental subsystems provide the necessary “environment” in which these applications can run. They are an essential part of the Windows NT operating system that enables cross-platform support for applications written for different operating systems. Windows NT, Windows 2000, Windows XP, and Windows .NET Server include the following environmental subsystems:

- Win32 subsystem for running 32-bit Windows applications
- OS/2 subsystem for running OS/2 1.X character-based applications (does not support the OS/2 Presentation Manager GUI or Warp versions)

- POSIX subsystem for running POSIX.1-compliant applications

Notes

MS-DOS-based applications run on Windows NT, Windows 2000, Windows XP, and Windows .NET Server in the context of a Win32 application called a Virtual DOS Machine (VDM) that emulates an MS-DOS environment.

environment variables

String variables containing information that an operating system uses to control services and applications.

Overview

Environment variables have been used in Microsoft operating systems since MS-DOS, where the PATH and TEMP variables used in the Autoexec.bat file were early examples. Microsoft Windows NT, Windows 2000, Windows XP, and Windows .NET Server offer a far more extensive selection of environment variables, including the following types:

- System (predefined) environment variables such as USERNAME, USERDOMAIN, WINDIR, and HOMEPATH. These variables are set on the system no matter who logs on and cannot be changed by any user. They specify particular parameters pertaining to the system itself, such as the location of the operating system files. They can be used in logon scripts because they are always present when any user logs on.
- User (user-defined) environment variables, such as the path to application files. User environment variables take precedence over system environment variables when the two conflict.
- Autoexec.bat environment variables, such as those used in path statements.

You can view and specify environment variables in Windows NT, Windows 2000, Windows XP, and Windows .NET Server by using the System utility in Control Panel. Environment variables may be used in logon scripts by enclosing them within percent symbols; for example, %USERNAME% contains the currently logged-on user name.

Notes

The System utility in Control Panel shows only a portion of the system environment variables defined on a system running Windows NT, Windows 2000, Windows XP, or Windows .NET Server.

ESMTP

Stands for SMTP Service Extensions, a set of extensions to the Simple Mail Transfer Protocol (SMTP) protocol.

Overview

ESMTP provides a series of enhancements to SMTP, including authentication between SMTP hosts, the ability to resume a connection that is interrupted without having to begin all over again (called checkpointing), and the ability to transmit multiple SMTP messages at once (called pipelining).

The ESMTP standard is defined in RFC 1869.

Implementation

ESMTP works by enabling the receiving host in an SMTP transmission to inform the sending host of what extensions it supports. Instead of beginning the session with the HELO command, the receiving host issues the EHLO command. If the sending host accepts this command, the receiving host then sends it a list of SMTP extensions it understands, and the sending host then knows which SMTP extensions it can use to communicate with the receiving host.

Implementing ESMTP requires no modification of the SMTP configuration of either the client or the mail

server. Most modern SMTP mail systems, including Microsoft Exchange, support ESMTP.

Ethernet

The most popular network architecture for local area networks (LANs).

Overview

Ethernet is a baseband networking technology that sends its signals serially 1 bit at a time. In its most basic form, Ethernet operates in half-duplex mode, in which a station can either transmit or receive but cannot do both simultaneously. Another form of Ethernet is full-duplex Ethernet, which uses two pairs of wires with Ethernet switches to allow stations to send and receive data simultaneously without collisions.

Ethernet specifications define the functions that occur at the physical layer and data-link layer of the Open Systems Interconnection (OSI) reference model and package data into frames for transmission on the wire. It is available in three speeds:

- 10 megabits per second (Mbps), which is simply called Ethernet
- 100 Mbps, which is called Fast Ethernet
- 1000 Mbps or 1 gigabit per second (Gbps), which is called Gigabit Ethernet (GbE)

Because of its simplicity and reliability, Ethernet is by far the most popular networking architecture used today.

History

Ethernet was originally developed by Xerox Corporation in the 1970s and was proposed as a standard by Xerox, Digital Equipment Corporation (DEC), and Intel Corporation in 1980. A separate standardization process for Ethernet technologies was established in 1985 in the Institute of Electrical and Electronics Engineers (IEEE) 802.3 standard known as Project 802. The IEEE standard was then adopted by the International Organization for Standardization (ISO), making it a worldwide standard for networking.

Ethernet in its original form, called Standard Ethernet (or 10Base5 or thicknet), was first commercially available in 1981 and standardized as 10Base5 in 1984. A version running on thinner coaxial cable called thinnet (or 10Base2) emerged in 1985 for workgroup LAN deployments, while thicknet remained the providence of campus backbones. The first commercial Ethernet bridges also appeared about 1985.

The next major advance was deploying Ethernet over unshielded twisted-pair (UTP) cabling. This occurred in 1990 with the standardization of 10BaseT Ethernet. A fiber version called 10BaseF was developed in 1993 but never really caught on as advances in technology allowed the speed of Ethernet to be increased tenfold two years later with the development of Fast Ethernet or 100BaseT. Meanwhile, in 1992 the first commercial full-duplex Ethernet products appeared in the marketplace.

The next advance was another tenfold increase in speed to 1000 Mbps or 1 Gbps. This was standardized in 1998 as GbE or 1000BaseX, which initially ran only over fiber but was extended in 1999 to run over copper as well in the form 1000BaseT.

Other significant advances in Ethernet technologies in the last decade include

- **Auto-negotiation:** This was developed in 1996 to support hybrid 10/100 Mbps Ethernet gear and has been extended to 10/100/1000 Mbps as well.
- **Ethernet switching:** The first Layer-2 switches became available in 1992, and VLAN (virtual LAN) features were added in 1998.

Architecture

Ethernet uses the Carrier Sense Multiple Access with Collision Detection (CSMA/CD) media-access control method for determining which station can transmit at a given time over the shared medium. In an Ethernet network, each station (computer) listens to the network and transmits data only if no other station is using the network. If the wire is free of signals, any station can contend (try to take control of) the network to transmit a signal. Ethernet networks are thus based on the concept of contention and operate on a first-come, first-served basis, rather than relying on a master station that controls when other stations can transmit. If two stations try to transmit data at the same time, a collision occurs, and both stations stop transmitting. They wait a random interval of time (measured in milliseconds) and then try again. The more stations on an Ethernet network, the higher the number of collisions, and the worse the network's performance. Typical performance of a 10-Mbps Ethernet network with 100 stations will support a bandwidth of only about 40 to 60 percent of the expected value of 10 Mbps. One way of solving the collision problem is to use Ethernet switches to segment an Ethernet network into smaller-collision domains.

Ethernet. *The Ethernet II frame format.*

Ethernet stations transmit data over the wire in packages called frames. An Ethernet frame has a minimum size of 64 bytes and a maximum size of 1518 bytes. A total of 18 bytes are used for information such as source and destination addresses, network protocol being used, and other frame overhead. Thus, the maximum payload size (amount of data carried) for an Ethernet frame is

1500 bytes. Ethernet packages data into a frame by four different Ethernet encapsulation methods:

- Ethernet II, used for Transmission Control Protocol/Internet Protocol (TCP/IP)
- Ethernet 802.3, called Raw 802.3 in Novell networking and used for connectivity with NetWare 3.11 and earlier
- Ethernet 802.2, also called Ethernet 802.3/802.2 without subnetwork access protocol (SNAP) and used for connectivity with NetWare 3.12 and later
- Ethernet SNAP, also called Ethernet 802.3/802.2 with SNAP and created for compatibility with Macintosh and TCP/IP systems

Implementation

Ethernet can use virtually any physical networking topology and cabling system (medium). Although a star topology (stations that are wired in a star-like configuration to a central hub) is often used from the physical point of view, all Ethernet networks are logical bus-topology networks at heart. One station places a signal on the bus, and that signal travels to every other station along the bus.

Ethernet is available in three speeds and can be further differentiated by media and other considerations, as shown in the table.

Ethernet Speeds, Types, Standards, and Specs

<i>Speed</i>	<i>Type of Ethernet</i>	<i>IEEE Standards</i>	<i>IEEE Specs</i>
10 Mbps	Ethernet	10Base2 10Base5 10BaseF 10BaseT	802.3
100 Mbps	Fast Ethernet	100BaseFX 100BaseT 100BaseT4 100BaseTX	802.3u
1000 Mbps or 1 Gbps	GbE	1000BaseCX 1000BaseLX 1000BaseSX 1000BaseT	802.3z

Ethernet media specifications such as 10BaseT may seem strange and obscure but can be easily interpreted.

For example, 10BaseT means **10**-Mbps baseband transmission over Twisted-pair cabling media.

Prospects

The prospects for the continuing evolution of Ethernet look strong. On the horizon is 10 GbE (10 Gbps Ethernet), which will probably become the next upgrade for enterprise network backbones. Another advance is the recent incorporation of Quality of Service (QoS) features into Ethernet using the 802.1p standard, making Ethernet more suitable for carrying delay-sensitive traffic such as voice an area that until now has been dominated by Asynchronous Transfer Mode (ATM).

Optical Ethernet is a new development that sees carriers such as Yipes extend high-speed Ethernet metropolitan area network (MAN) and wide area network (WAN) connections to businesses in metropolitan areas, eliminating the need for costly Ethernet-to-ATM/Synchronous Optical Network (SONET) access devices and turning corporate WANs into large Ethernet local area networks (LANs).

Another amazing development is that Ethernet is being considered in some quarters as a bus technology to replace PCI for computer system buses. One company involved in this development is Performance Technologies.

Where Ethernet will finally hit the wall and be replaced by some other technology is anyone's guess. In the past 20 years, Ethernet has delivered all but knockout blows to its competitors in the LAN arena, including Token Ring, Fiber Distributed Data Interface (FDDI), and ATM. Whether it can do the same in the WAN arena reamins still in question, but it is bound to be an exciting fight.

Notes

The various Ethernet framing formats are incompatible, so if you have a heterogeneous Ethernet network, you must specify the correct frame type to allow machines running Microsoft Windows NT to see your Novell NetWare servers. Windows NT allows you to select Auto Detect from the Frame Type drop-down list on the NWLink IPX/SPX-Compatible Transport protocol configuration property sheet if you do not know what frame type your NetWare servers are using. (In Windows 2000, Windows XP, and Windows .NET Server, select the check box next to Auto Frame

E

Type Detection in the NWLink IPX/SPX/NetBIOS-Compatible Transport protocol configuration property sheet.) You might also need to configure your routers for the proper frame type. Older Cisco routers running Internetwork Operating System (IOS) version 10 or earlier do not support Ethernet 802.3/802.2 with SNAP.

The table shows some troubleshooting tips for Ethernet media problems.

Troubleshooting Tips for Ethernet Media Problems

<i>Problem</i>	<i>Suggestion</i>
No link integrity	Check that you have not mismatched 10BaseT and 100BaseT (or 100BaseTX and 100BaseT4) cables, hubs, or network interface cards; that ensure no crossover cables are used for station-to-hub cable connections.
Too much noise	Check for damaged cables; ensure you are using Category 5 (Cat5) cabling (or enhanced Cat5 [Cat5e] cabling for 100BaseT) and that all your cabling interface components (patch panels, wall plates, terminal blocks, and so on) are Cat5 certified.
Too many collisions (greater than 0.1 percent of total frames on the network)	Check for unterminated cables using a time-domain reflectometer; use a protocol analyzer to look for a jabbering transceiver (a network interface card that is continually broadcasting); and ensure that cables exceed the maximum specified length.

Ethernet Industrial Protocol (Ethernet/IP)

A new standard that allows Ethernet and Transmission Control Protocol/Internet Protocol (TCP/IP) to be used for automation networks within industrial plants.

Overview

The Ethernet Industrial Protocol (Ethernet/IP) was developed by the Open DeviceNet Vendor Association, spearheaded by Rockwell Automation. Ethernet/IP is designed to allow commodity Ethernet equipment and TCP/IP software to be used for connecting industrial controllers and automation devices on factory floors. For example, using Ethernet/IP, a programmable logic controller and sensor can be used to remotely control an assembly-line robot tool using IP running over a switched Ethernet network. Other devices that might be used on an Ethernet/IP network include bar-code readers, automated weigh scales, stepping motors, and so on. More generally, Ethernet/IP can be used to tie in a company’s industrial control network with its corporate business network, thus automating the exchange of information between inventory control systems and shipping systems for assembly-line processes.

Ethernet/IP is designed to replace an existing industrial controller network protocol called ControlNet, which was developed some years ago by Rockwell Automation and has found widespread acceptance in robotic and industrial environments.

Implementation

Ethernet/IP works by encapsulating messages from two industrial automation protocols, ControlNet and DeviceNet. Ethernet/IP employs the same application layer protocol as these two protocols, namely Control and Information Protocol (CIP). The CIP protocol runs on top of the network layer protocols TCP (used for

explicit messaging between controllers and devices) and User Datagram Protocol (UDP) (used for implicit messaging). Ethernet/IP supports both real-time and asynchronous messaging as well as client/server and peer-to-peer messaging.

Ethernet/IP is usually implemented as a switched Ethernet fabric using full-duplex communications. This is necessary because the latency caused by contention in traditional Ethernet networks can have a detrimental effect on time-sensitive industrial assembly-line processes.

Advantages and Disadvantages

The advantage of Ethernet/IP over traditional automation networks is that cost savings can be achieved by running both the corporate network and the automation network using the same technology, namely Ethernet. Ethernet/IP allows control messages to be delivered across a plant floor using off-the-shelf Ethernet gear and without the need to develop custom Ethernet-to-ControlNet gateways. This helps industrial businesses leverage Ethernet's low cost, proven operation, and high bandwidth.

Special training in automation protocols is not required, and only one set of gear needs to be deployed and kept in stock.

Marketplace

Some of the bigger vendors that offer Ethernet/IP-enabled controllers and interfaces are Rockwell, MicroLogix Information Systems, and FLEX I/O.

Ethernet switch

A multiport device based on bridging technologies that is mainly used to segment Ethernet networks.

Overview

Often simply called switches (when referring implicitly to Ethernet networking), these devices are used to enhance the performance of Ethernet networks. An Ethernet switch basically resembles a hub, and consists of a box with a number of RJ-45 jacks on the front to provide ports for network connections. Inside, however, are advanced electronics that generally make switches more costly than hubs.

In a hub, a packet entering one port is regenerated and forwarded to every other port. While the packet is being forwarded, no other port can receive packets, so a hub can be thought of as a shared-media device in which all ports are connected using a shared bus. If a collision occurs on a hub-based Ethernet network, no port on the hub can receive traffic until the collision is resolved. The set of stations connected to a hub is thus called a collision domain. On the average, if a 10-megabits-per-second (Mbps) Ethernet hub has 10 ports, each port effectively gets one-tenth of the total bandwidth, or 1 Mbps. In reality this can be much worse, however, for a single station actively transferring files can consume a large percentage of the available 10 Mbps bandwidth of the hub, leaving other stations starved for bandwidth for their communications. Hub-based Ethernet networks are thus based on contention in which every station must fight for its share of bandwidth.

If you connect several hubs and their networks by uplinking them to a main hub, the situation only gets worse because the new larger network remains a single collision domain. With the increased number of nodes on the network, however, more collisions are likely to occur and network traffic congestion can result, slowing the network to a crawl.

The solution to this congestion problem is to strategically use Ethernet switches in place of, or in addition to, hubs. When a packet enters a port of an Ethernet switch, the switch looks at the frame's destination address, compares it to a table of address-to-port mappings

E maintained internally by the switch, internally establishes a temporary internal logical connection between the incoming port where the packet arrived and the outgoing port where the packet is destined, and forwards the packet along this internal connection to its destination. Only the port where the packet arrived and the destination port are involved in this process; all other ports on the switch have no part in the connection.

The result of this process is that each port on the switch corresponds to an individual collision domain, and network congestion is therefore avoided. Thus, if a 10-Mbps Ethernet switch has 10 ports, each port effectively gets the entire bandwidth of 10 Mbps, and to an incoming packet the switch's port appears to provide a dedicated connection to the destination node on the network.

In other words, replacing switches with hubs does not add bandwidth to your network. Instead, it reduces the size of collision domains to allow bandwidth to be used more efficiently. If 12 stations are connected to a 12-port 10 Mbps hub, the maximum bandwidth any one station can theoretically use is 10 Mbps, but if a station were actually using this much bandwidth, all remaining stations connected to the hub (except for the station being communicated with) would have zero bandwidth available to them. If a 12-port, 10 Mbps switch were used instead of the hub, however, all 12 stations could participate in 10 Mbps conversations simultaneously, which means the switching fabric supports $12 \text{ ports} = 6 \text{ communications} \times 2 \text{ ports/communication} = 6 \times 10 \text{ Mbps} = 60 \text{ Mbps throughput}$. However, the total bandwidth available to any one station is still only 10 Mbps, no more than for the hub. The difference is that this 10 Mbps bandwidth is guaranteed to be always available for each station!

Architecture

A basic Ethernet switch operates at Layer 2 (the data link layer) of the Open Systems Interconnection (OSI) model. Like a bridge, an Ethernet switch is a smart device that can learn the media access control (MAC) address of each connected station by listening to network traffic. The switch builds an internal table listing the MAC address of each port and consults this table when it needs to forward incoming packets.

Ethernet switch. Comparison between how a hub and an Ethernet switch work.

When an Ethernet frame arrives at a port, the destination MAC address is read from the first 64 bits of the frame. This destination address is then found in the switch's internal address table to determine the correct destination port for the frame. Once this is determined, the switching fabric (a mesh-like connection) inside the switch establishes a temporary logical connection between the incoming and destination ports, forwards the frame, and then tears down the connection. Ethernet switches are also capable of establishing multiple internal logical connections simultaneously between differ-

ent pairs of ports. The result is that each port receives the switch's full dedicated bandwidth at all times, giving Ethernet switches intrinsically much more bandwidth than shared hubs.

The actual mechanism by which switching (the forwarding of the packet between the ports) occurs divides Ethernet switches into two general device classes:

- **Store-and-forward switches:** This type waits until the entire incoming frame arrives, buffers the frame, reads the destination address from the buffered frame, performs cyclical redundancy check (CRC) error checking to verify that the frame is valid, and either forwards the frame to the destination port using the switching fabric or drops the frame if it represents a runt, jabber, or some other invalid frame. Store-and-forward is the same method by which most bridges work. The advantages of this method are that bad frames are eliminated and collisions are handled well, while the disadvantage is that it suffers from high latency (delay) because the frame must be entirely read and buffered before being processed. Nevertheless, most switches used today are of the store-and-forward type, and Transmission Control Protocol/Internet Protocol (TCP/IP) is generally well able to handle any additional latency that arises in networks due to use of these switches.
- **Cut-through switches:** This type reads the frame as it comes into the receiving port, and after the source and destination addresses are read from the first 64 bits, the switch then checks the internal address table and immediately forwards the frame to the correct destination port. Error checking is not performed by cut-through switches, since to perform this check the CRC byte would have to be read first, and this is located at the end of the frame. As a result of not performing error checking, cut-through switches reduce latency and accelerate performance over store-and-forward switches, but the result is that collisions can affect overall communications and bad frames are passed rather than dropped. The earliest Ethernet switches were of the cut-through type and found particular application in NetWare

3.x networks where Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) was less tolerant to delay than Internet Protocol (IP). Limitations in bridging electronics also made cut-through switching appealing in the earliest implementations, but advances in electronics have made store-and-forward switching more appealing. The first commercial Ethernet switches were cut-through switches developed in 1990 by Kalpana, which is now a subsidiary of Cisco Systems.

Implementation

Ethernet switching (or switched Ethernet) can be implemented in various ways depending on the OSI layers at which the switches operate. These include

- **Layer-2 switch:** This basic Ethernet switch operates at the OSI data-link layer (Layer 2) and is based on bridging technologies as explained above. Layer-2 switches establish logical connections between ports based on MAC addresses and are generally used for segmenting an existing network into smaller collision domains to improve performance.
- **Layer-3 switch:** This type operates at the OSI network layer (or Layer 3) and is based on routing technologies. Layer-3 switches establish logical connections between ports based on network addresses such as IP addresses. You can use Layer-3 switches instead of routers for connecting different networks into an internetwork, and they generally perform better than routers due to their enhanced electronics. Layer-3 switches are sometimes called routing switches, multilayer switches, or sometimes simply routers.
- **Layer-4 switch:** This is basically an enhanced Layer-3 switch that has the additional capability of examining the source and destination ports of Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) connections and making forwarding decisions based on this information. They are called Layer-4 switches because they examine OSI transport layer (Layer 4) information within frames and determine how to forward the frames based on this information.

- Layer-7 switch:** In this type of device the entire frame is unpackaged to determine OSI application layer (Layer 7) information such as what application layer protocol is being used, such as Hypertext Transfer Protocol (HTTP) or File Transfer Protocol (FTP). Frames can then be forwarded or dropped based on this information.
- Multilayer switch:** This is simply a switch that uses unpackaged frame information from several OSI layers to determine how to forward frames. For example, most Layer-4 switches are actually Layer-3/4 switches since they operate at both layers.

Ethernet switches are also distinguished in other ways, such as by the number of ports they have, whether they operate in half-duplex or full-duplex mode, their transmission speed (for example, 10 Mbps, 1/100 Mbps, or 100/1000 Mbps), ports for connectivity with high-speed Fiber Distributed Data Interface (FDDI) backbones, and so on. Advanced features can include Simple Network Management Protocol (SNMP), out-of-band management (OBM), and custom packet filtering.

Uses

Ethernet switches have two basic uses: segmenting networks to improve performance and interconnecting networks of different speeds. The most common use is network segmentation, and introducing Ethernet switches will provide the most obvious benefit for parts of your network where the most contention occurs. For example, if you have several heavily used servers on the same hub-based local area network (LAN) as clients, the clients have to contend for use of the servers and the result is poor performance. To improve things, segment your LAN into several collision domains, one for each hub and one for each group of clients, as shown in the figure. Now several clients can connect to different servers simultaneously and receive the full throughput of those servers. A good rule of thumb for deciding whether to use switches to segment your existing network is that switches can improve your network's performance if the current network utilization level is higher than 35 percent or if collisions are running at more than 10 percent.

Ethernet switch. Improving performance of a hub-based LAN by using an Ethernet switch.

The second main use for switches is to connect fast workgroup hubs to slower hubs on a network. Again, the main hub is replaced by an Ethernet switch, typically 10/100 or 100/1000 Mbps, and the performance of

stations on the fast hub is no longer hindered by the presence of the slower parts of the network. Another related use for Ethernet switches is to connect 100-Mbps Ethernet “islands” to an existing 10-Mbps Ethernet LAN. Simply use a 10/100-Mbps Ethernet switch with two ports to connect them. You can also connect two LANs several kilometers apart by using two Ethernet switches, both having one 100BaseT port and one 100BaseFX port. Connect the switches to the LANs, and then connect a fiber-optic cable between the FX ports.

If users in a department have high bandwidth needs, such as those running computer-aided design (CAD) or multimedia applications, consider replacing their workgroup hub with an Ethernet switch, or if the number of users is small, connect their stations directly to the main Ethernet switch.

When purchasing Ethernet switches, make sure they have Remote Monitoring (RMON) agents built into each port, which will considerably ease remote network troubleshooting.

Marketplace

Ethernet switches are made all shapes and sizes from dozens of different vendors. They vary from small 12-port 10/100 workgroup switches to modular 1 Gbps backbone switches supporting Asynchronous Transfer Mode (ATM) and Synchronous Optical Network (SONET) connectivity. Probably the most popular 10/100 Ethernet switches are those of the Cisco Catalyst 3500 Series XL, which by some counts are deployed twice as often as any other type of similar switch from other vendors. A popular enterprise switch used for collapsed backbones is the Big Iron 4000 switch from Foundry Networks. Another widely deployed backbone switch is the Hewlett-Packard 9304.

Issues

Although Ethernet switches relieve traffic congestion by segmenting collision domains, they do have some disadvantages:

- They are generally several times more expensive than hubs of the same speed.
- Networks involving switches are more difficult to monitor and troubleshoot.

Ethernet switches should generally be implemented judiciously within Ethernet networks. Simply replacing every hub with a switch is an unnecessary expense that brings negligible performance enhancement over just replacing a few key hubs with switches.

event

Any operating system or software condition that is logged by the Event Logging service of Microsoft Windows 2000, Windows XP, and Windows .NET Server.

Overview

You can view events by using the administrative tool called Event Viewer. There are five basic types of events:

- **Errors:** These events represent a significant problem that can lead to loss of data or functionality in the operating system, such as failure of a service to start upon reboot. The corresponding symbol in the system or application log is a red stop sign.
- **Warnings:** These events indicate some impending problem such as low remaining disk space. The

corresponding symbol in the system or application log is an exclamation point superimposed on a yellow circle.

- **Information:** These events indicate that a significant system operation has successfully occurred for example, a service has started. The corresponding symbol in the system or application log is an information sign—that is, the letter *i* superimposed on a blue circle.
- **Successes:** These events are recorded only in the security log and represent auditing information concerning the successful completion of attempts to access secured resources, such as when a user logs on to the network.
- **Failures:** These events are recorded only in the security log and represent auditing information concerning failed attempts to access secured resources, such as when a user attempts to access a shared folder and fails.

Everyone group

A system group existing on all Microsoft Windows NT, Windows 2000, Windows XP, and Windows .NET Server servers and workstations.

Overview

The Everyone group is one of seven (additional new groups exist on Windows XP and Windows .NET Server) built-in system groups that are defined on networks based on the Windows 2000, Windows XP, and Windows .NET Server operating system and includes all local and remote users. This includes users from trusted domains and non-Windows networks. By default, the Everyone system group has the sole preassigned system right “Access this computer from network.” You can grant additional rights to this group if desired. You cannot modify the membership of system groups such as the Everyone group directly.

Notes

When you share a folder on a server running Windows 2000 or Windows .NET Server, or on a workstation running Windows XP, full control permission is initially assigned to the Everyone group. It is advisable to remove

this group and assign appropriate permissions to other groups, such as Administrators and Users.

Be careful about assigning additional permissions to the Everyone group. If you allow users who do not have valid user accounts to access the network using the Guest account, they will gain any permissions and rights assigned to the Everyone group.

Exchange Server

Microsoft Exchange Server 2000 is Microsoft Corporation’s premier messaging and collaboration solutions-building platform for Windows 2000. Exchange 2000 is part of the Microsoft BackOffice suite of server applications. Exchange Server is designed for mission-critical enterprise-level messaging solutions and includes such features as

- Intelligent message rerouting
- Transaction-based directory services
- Fault-tolerant message store
- Built-in server and link monitoring tools
- Connectors and gateways for connectivity with foreign mail systems

Exchange 2000 can coexist with most popular and legacy mail systems and can be used for messaging connectivity with the following:

- Microsoft Mail
- Internet mail (Simple Mail Transfer Protocol [SMTP])
- X.400
- Lotus cc:Mail
- IBM PROFS and SNADS

Exchange 2000 supports all key industry messaging standards, including:

- Internet messaging standards such as SMTP, Post Office Protocol 3 (POP3), Internet Message Access Protocol 4 (IMAP4), Lightweight Directory Access

Protocol (LDAP), Hypertext Transfer Protocol (HTTP), Network News Transfer Protocol (NNTP), Secure Sockets Layers (SSL), Multipurpose Internet Mail Extensions (MIME), and Secure/Multipurpose Internet Mail Extensions (S/MIME)

- X.400 messaging standards
- Microsoft's Messaging Application Programming Interface (MAPI)

The Microsoft Outlook 2000 client software, part of the Microsoft Office 2000 suite of business productivity tools, complements Exchange Server by providing users with a full desktop information-management tool for managing messages, appointments, tasks, and contacts. Although the preferred client for Exchange 2000 is Outlook 2000, Exchange clients are available for all the popular operating systems, including MS-DOS, Windows 3.x, Windows 95, Windows 98, Windows NT, Windows 2000, Apple Macintosh, UNIX, and OS/2. Note that the features supported by different clients vary with the platform used.

History

Exchange 4 replaced Microsoft Mail 3.51 in 1996 as Microsoft's client/server messaging and collaboration system. Exchange 4 employed an X.500-based directory and natively supported the SMTP, MIME, MAPI, and X.400 messaging standards, with X.400 being the underlying message transport protocol. In 1997, Exchange 5 was released, which supported additional Internet standards such as POP3 for mailbox access, NNTP for Usenet newsgroups, LDAP for X.500 directory access, HTTP and HTML for Web browser access, and SSL for secure authentication and encryption. Later in 1997 Exchange Server 5.5 added support for Microsoft Cluster Server, IMAP4 and S/MIME protocols, Key Management services, Virtual Organizations, and unlimited message store size.

Exchange 2000 was a radical departure from early versions because it eliminated the proprietary Exchange directory and instead tightly integrated Exchange with Windows 2000's Active Directory directory service. Exchange 2000 includes the Web Storage System, which provides a hierarchical data storage mechanism

that incorporates Extensible Markup Language (XML) as part of its specification. Exchange 2000 also tightly integrates with Internet Information Services (IIS), Microsoft's Web services platform and uses IIS as its Internet messaging protocol handler. Exchange 2000 is available in several editions and can be deployed in various ways, including as a messaging system for small companies, a platform for building collaborative workflow applications for large enterprises, Internet mail servers for Internet service providers (ISPs), and hosted messaging and collaboration services offered by Application Service Providers (ASPs).

experience

A modern term used to describe applications that have an interface designed for the user.

Overview

The term *experience* has recently come into common use in programming parlance to describe any application that has a customizable user interface. Developers who work on client software are thus "developing experiences" for the users of their software.

The term *experience* is also used in the discussion of Microsoft Corporation's .NET platform to mean the delivery of integrated functionality to users through Web services. The .NET platform is designed to allow developers to build compelling user experiences that will provide sets of targeted functionality to bring about the next phase of the Internet's evolution. Some of the pieces already in place to provide this experience include

- bCentral, a resource for small businesses
- MSN (the Microsoft Network), targeted for consumers
- Microsoft Office, aimed at knowledge works
- Visual Studio.NET, targeted for developers

Notes

The term *user experience* is also commonly used to describe the visual appearance and interactivity of software for the Apple Macintosh platform, particularly Aqua in Mac OS X.

extended partition

A physical disk partition on which a series of logical drives can be created.

Overview

You can create an extended partition on a disk to overcome the limitation of having only four partitions per disk. Information about the various partitions on a disk is stored in a structure called the partition table. The partition table is 64 bytes in size and is located on cylinder 0, head 0, sector 1 of your hard drive, in the same sector as the Master Boot Record. The partition table has the same format no matter what operating system is used on the disk. Up to four partitions can be created on a disk, but only one partition can be extended per disk. In Microsoft Windows 2000, Windows XP, and Windows .NET Server, you can create an extended partition using Disk Management console. For earlier Windows platforms, use the fdisk utility.

Notes

In Windows 2000 and Windows XP, and Windows .NET Server, extended partitions can be created only on basic disks.

Extended Turn (ETRN)

An enhancement for Simple Mail Transfer Protocol (SMTP) to enable SMTP hosts to initiate mail transfers with one another.

Overview

SMTP hosts were originally envisioned as machines that always had to be connected to the Internet using dedicated connections such as leased lines. In this scenario, when a host must send mail to another host on the Internet, it simply does so, assuming the other host is there and is listening to receive any mail forwarded to it.

With the advent of companies wanting to connect their SMTP hosts to the Internet using dial-up connections to save money over leased lines, some mechanism had to be developed to allow a host to tell other hosts that it was online and ready to receive mail. Extended Turn (ETRN) was developed for this purpose. For example, a company may configure its SMTP host to dial up to the company's Internet service provider (ISP) and issue an ETRN command to the ISP's remote host to deliver mail queued on the remote host.

Issues

ETRN is a stopgap solution that was added to SMTP to work around the problem described above. ETRN has several disadvantages, including its complexity to configure and its requirement for a permanent Internet Protocol (IP) address for the dial-up server. A much better solution for downloading corporate mail from an ISP's SMTP host is to use a Post Office Protocol 3 (POP3) server instead.

extender

A general name for a class of networking devices that extend the distances over which stations (computers) can typically be connected to concentrators such as hubs and switches.

Overview

An example of an extender is a 10BaseT extender for Ethernet networks. In 10BaseT networks, stations should be located no more than 328 feet (100 meters) from a hub, but by using an extender, you can increase this to about 600 feet (183 meters). A 10BaseT extender can thus be used for connecting a remote station, such as a station located in a nearby building, to the network. Extenders are essentially a simplified form of bridge designed to support only a few remote stations. They must be installed in pairs, one at the remote location and one at the main network. Some extenders can be used to carry network data over installed phone lines, connecting remote stations without installing additional network cabling.

Extender. Using an extender to join a remote station to a local area network (LAN).

Extenders are also available for increasing the maximum connection distance for other data transmission technologies such as the Small Computer System Interface (SCSI) bus. A normal SCSI bus is limited to about 20 feet (6 meters), but a fiber-optic SCSI extender can increase this distance to 0.6 mile (1 kilometer) or more using duplex fiber-optic cable. You can use parallel extenders for directly connecting to printers located in a different building. You can use serial extenders to connect computers to remote RS-232 serial test equipment located in laboratories in different buildings.

Extensible Authentication Protocol (EAP)

A security enhancement of Point-to-Point Protocol (PPP).

Overview

Extensible Authentication Protocol (EAP) is an extension to PPP specified in RFC 2284. EAP allows for an arbitrary authentication method to be negotiated during initialization of a PPP session. This is accomplished during the Link Control Protocol (LCP) negotiation portion of the PPP session establishment sequence. EAP allows third-party security products to be used to provide addi-

tional security to PPP sessions using special application programming interfaces (APIs) built into operating systems whose implementation of PPP supports EAP.

EAP is designed to make remote access and virtual private network (VPN) communications more secure by allowing any kind of authentication to be used, including

- Smart cards such as Fortezza, SecurID, and other token technologies.
- MD5-CHAP, which provides 128-bit encryption during authentication.
- Kerberos authentication, the standard authentication method for Windows 2000, Windows XP, and Windows .NET Server.
- Transport Layer Security (TLS), which is implemented in Web browsers, smart cards, biometric authentication devices, and so on.

In Microsoft Windows 2000 and Windows .NET Server, EAP is supported by both the Routing and Remote Access Service (RRAS) and Internet Security and Acceleration (IAS) services and by dial-up networking (DUN). Each type of EAP authentication method allowed is implemented through specific plug-in modules designated dynamic-link libraries (DLLs) on both the client and the server. So if you purchase a smart card system from a vendor for use with Windows 2000 or Windows .NET Server remote access, you run the vendor's Setup program on both your DUN client and Remote Access Service (RAS) server to install the necessary EAP DLLs.

Extensible Firmware Interface (EFI)

A new firmware standard for 64-bit Intel processors.

Overview

Extensible Firmware Interface (EFI) is a new standard for the firmware that is used to boot PCs using Intel Corporation's new 64-bit Itanium processor family. EFI is required for all Itanium-based systems that will run

Microsoft's new 64-bit Windows platform because these systems cannot boot using the basic input/output system (BIOS) or System Abstraction Layer (SAL) alone. EFI will be supported in all 64-bit versions of Microsoft Windows.

extension cable

A cable used to extend a length of cabling.

Overview

Extension cables are available in all types with various connector devices and can be used to extend serial lines, parallel lines, network cables, power cables, and other cords.

Extending a cable using an extension cable is not always a good idea because the additional interface introduced by the connection usually results in some signal loss. Furthermore, extending network cables can cause problems if the new, longer cable exceeds the maximum length of the specifications for that type of network. For example, extending unshielded twisted-pair (UTP) cabling beyond 328 feet (100 meters) in a 10BaseT Ethernet network can result in unreliable communication between hosts on the network.

Exterior Border Gateway Protocol (EBGP)

The version of Border Gateway Protocol (BGP) used for exchanging routing information between different autonomous systems.

Overview

There are two versions of BGP, the classless dynamic routing protocol used on the Internet. These versions are

- **Exterior Border Gateway Protocol (EBGP):** This is an exterior routing protocol that is used for exchanging routing information dynamically between border routers connecting autonomous systems (ASs) on the Internet or in a large private Transmission Control Protocol/Internet Protocol (TCP/IP) internetwork. When referring simply to BGP, the variant EBGP is always implied. In other words, EBGP is usually just called BGP.
- **Interior Border Gateway Protocol (IBGP):** This is an interior routing protocol that is used for exchanging routing information between routers within an AS.

See Also: autonomous system (AS), Border Gateway Protocol (BGP), classless routing protocol, dynamic routing

exterior gateway protocol (EGP)

Any routing protocol used to distribute routing information between autonomous systems.

Overview

Also known as exterior routing protocols, exterior gateway protocols (EGPs) specify how different autonomous systems (ASs) within large Transmission Control Protocol/Internet Protocol (TCP/IP) internetworks such as the Internet communicate with each other to exchange routing information. EGPs facilitate the exchange of inter-autonomous-system routing information between different autonomous systems, independent of which interior gateway protocols (IGPs) are used within these autonomous systems.

There are two EGPs for IP internetworks:

- **Exterior Gateway Protocol (EGP):** This is the original EGP developed in the early days of the Internet to facilitate the Internet's growth. Note the

confusing use of the term *Exterior Gateway Protocol (EGP)* here—EGP stands both for the general category of inter-AS routing protocols and also for the first actual protocol developed within this category. In other words, EGP is one of two examples of an EGP! For more information, see the second article titled “Exterior Gateway Protocol (EGP),” which is the next entry in this chapter.

- **Border Gateway Protocol (BGP):** This is a newer EGP that has replaced the Exterior Gateway Protocol for inter-AS communication on the Internet.

Exterior Gateway Protocol (EGP)

The original exterior routing protocol used to connect autonomous systems on the Internet.

Overview

Exterior Gateway Protocol (EGP) was the original interdomain routing protocol developed for communicating routing information between autonomous systems on the Internet. In fact, the idea of autonomous systems was developed in conjunction with EGP.

EGP was developed in 1982 for the ARPANET, the precursor to the Internet, and was conceived at a time when the Internet was envisioned as a single core network to which various other networks were connected. The developers of the Internet saw early on that scaling problems would occur as the Internet grew in size and complexity, and so the idea of apportioning the Internet into separate sections called autonomous systems (ASs), each under someone else’s authority, was developed. Large private internetworks connected to the Internet were assigned autonomous system numbers (ASNs), and the core network itself was divided into several ASs.

To facilitate exchange of routing information between routers connecting these different networks, the concept

of dynamic routing was introduced and two kinds of dynamic routing protocols were developed:

- **Interior gateway protocols (IGPs):** These are used for routing within an AS and are thus intra-AS routing protocols. IGPs allow the routers within an AS to exchange routing table information with each other dynamically. Examples of IGPs include Routing Information Protocol (RIP) and Open Shortest Path First (OSPF).
- **Exterior gateway protocols (EGPs).** These are used for routing between different ASs and are thus inter-AS or interdomain routing protocols. EGPs allow routers on the borders between different ASs to exchange routing table information with each other dynamically. Examples of EGPs include Exterior Routing Protocol (EGP), from which the more general category EGP was later derived, and Border Gateway Protocol (BGP), the EGP commonly in use on the Internet today.

Implementation

Exterior Gateway Protocol, as defined in RFC 904, is based on the distance vector routing algorithm, but has the limitation that it only maintains information about a single route between two different ASs. EGP thus assumes that only a single path exists between any two ASs within the Internet, a condition that was seen early on as unrealistic. EGP also does not indicate the cost of the route between two ASs, only whether the route is reachable or unreachable. Furthermore, EGP supported only classless routing, and when it was implemented it was already obvious that the class A/B/C system of allocating Internet addresses would soon exhaust available addresses. As the Internet grew it became more complex in its structure as multipath connections between ASs began to develop. EGP’s weakness was quickly realized and BGP was developed to replace it. BGP also supports Classless Interdomain Routing (CIDR), which superseded the Internet’s earlier classful routing system.

Today EGP is considered a legacy routing protocol and is no longer used on the public Internet, although it is

probably still used in some large private Internet Protocol (IP) internetworks that have seen no real need for upgrading to BGP. Interestingly enough, as of 2001 EGP was still being used for MILNET, the public portion of the U.S. Defense Data Network.

extranet

A private Transmission Control Protocol/Internet Protocol (TCP/IP) network that securely shares information using Hypertext Transfer Protocol (HTTP) and other Internet protocols with business partners.

Overview

An extranet is basically a corporate intranet that is securely exposed over the Internet to specific groups that need access to it. Extranets are powerful tools because they let businesses share resources on their private networks over the Internet with suppliers, vendors, business partners, and wholesale customers. Extranets are typically used for supporting real-time supply chains, for enabling business partners to work together, and to share information such as catalogs with customers. Extranets basically comprise the B2B (business-to-business) portion of an e-business system, and building an extranet is an essential step for companies who want to compete in today's Internet economy.

Implementation

Extranets built on the corporate intranet model follow the client/server paradigm, with Web servers such as Microsoft Internet Information Services (IIS) functioning as the server, and Web browsers such as Microsoft Internet Explorer functioning as the client. Other extranet models exist, however, such as a peer-to-peer business connection for electronic data interchange (EDI). Peer-to-peer extranets between business partners typically use virtual private networks (VPNs) to establish secure, encrypted communication over the unsecured Internet for the transmission of sensitive business information, such as EDI between partners, or between headquarters and branch offices. These extranets act as dedicated gateways between business partners and generally do not allow private access to individual users. Peer-to-peer extranets can use Internet Protocol Security (IPsec) with a public key infrastructure (PKI) to provide IP-based authentication and encrypted transmission of information.

Client/server extranets have different requirements, however, because individual users must be authenticated before receiving secure, encrypted access to company resources. Instead of authenticating on the basis of IP addresses as in peer-to-peer extranets, users must be authenticated using user accounts or digital certificates mapped to accounts. Client/server extranets might support HTTP access only or might allow other client/server applications to run. Encryption for HTTP access is performed using the Secure Sockets Layer (SSL) protocol.

Although a basic extranet can be built easily by scripting a Web server to run as a front end for a corporate database, real-world extranets are often more complex. The difficult part is to build the extranet back into the back-end database systems and other sources of business information that business partners need to access. Virtual Private Network (VPN) and firewall technologies are commonly used to provide secure access between different partners over the Internet, and Extensible Markup Language (XML) is emerging as an

essential tool for structuring business information for exchange between partners. Extranets also often need to be coupled with directory services for managing access to information through policy-based mechanisms.

Advantages and Disadvantages

The power of the extranet is that it leverages the Internet's existing technology to increase the power, flexibility, and competitiveness of businesses using well-known and easily used tools such as Web servers and Web browsers. Extranets also save companies money by allowing them to establish business-to-business connectivity over the Internet instead of using expensive dedicated leased lines. Extranets can also save money by reducing phone and fax costs.

Marketplace

A new breed of policy-based access management tools has emerged for providing the infrastructure needed to build large directory-enabled extranets. Two popular products in this arena are GetAccess from enCommerce and SiteMinder from Netegrity. The Microsoft BizTalk framework and its associated server platform is seen as a key player in the emerging XML-ization of business extranets and other B2B services.

failback

In clustering technology, the action of moving resources back to a failed node or primary node (a computer in a cluster) once it has been recovered. This action can take place manually or automatically depending on how the cluster is configured.

Overview

Suppose you have a cluster that has two nodes, each containing different resources. If Node A experiences failure, failover occurs and the workload of Node A (its set of resources) is transferred to Node B. When Node A reboots, it checks with Node B to see which resources are running on Node B and discovers that some of these cluster groups would “prefer” to reside on Node A. At this point failback will occur if the cluster is configured to failback automatically if the primary node recovers. The preferred groups are then moved from Node B back to Node A. Failback might be configured to occur immediately or at a scheduled time if access to resources is low.

Notes

Failback is sometimes known as “rebalancing the workload.”

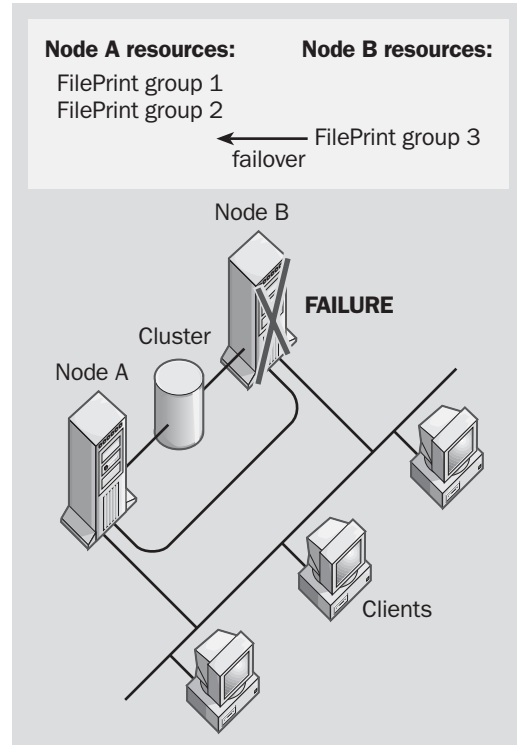

See Also: clustering, failover

failover

Any technology that allows one device to take over for a similar device that has failed.

Overview

An example of a typical failover system would be a failover cluster. Failover is also often used to ensure that a break in a communication line does not cause a break in communication between networked systems.

Failover. How failover works.

Suppose you have a cluster that has two nodes, each containing different resources. If Node B experiences failure, failover occurs and the workload of Node B (its set of resources) is transferred to Node A. In Microsoft Corporation’s clustering services (Microsoft Cluster Server for Microsoft Windows NT 4 Enterprise Edition and the Cluster service for Windows 2000 Enterprise Server and Datacenter Server and Windows .NET Server Enterprise Server and Datacenter Server), the cluster resources (network applications, data files, and other tools installed on the nodes of the cluster) provide

services to clients on the network. A resource can be hosted on only one node at any given time, but by using the Cluster Administrator program, you can configure the resource to failover to the second node if the first node fails. This causes the resource and its operation to move from one node to the other if a failure of one node occurs.

F

Failover is initiated automatically by the Cluster service when a failure is detected on one of the nodes. This process can take up to 10 seconds to initiate. Failover is transparent to the users if they are accessing cluster resources using stateless protocols such as Hypertext Transfer Protocol (HTTP) and does not require any special client software to be installed on users' machines. If a client is connected using a tool such as Windows Explorer, it will be notified that the connection is unavailable. The user should abort, retry, or cancel the connection attempt. (To connect to the resource on the failover node, retry the connection attempt.) For other Cluster service applications, users might have to log on again to the resource.

Notes

Microsoft's clustering services support failover at the level of virtual servers, which means items such as Web sites, print queues, file shares, and applications can be protected from system failure.

fallback switch

A class of switches used to provide failover support for critical network communication lines.

Overview

Fallback switches are an essential component of a fault-tolerant network system with resources that must have a high availability. In such a scenario, resources can be connected to your network using two circuits:

- A primary line that normally provides access to the resource
- A secondary line to which the fallback switch reroutes the moment the primary line fails

Fallback switch. Using a fallback switch.

Uses

Fallback switches can also be used to provide fault tolerance for a high-speed backbone for Fast Ethernet, Fiber Distributed Data Interface (FDDI), or Asynchronous Transfer Mode (ATM) networking. For example, you can use fallback switches to run two multimode fiber-optic cables between a pair of Ethernet switches, instead of having only one cable connecting them. If one fiber-optic cable goes dark, the fallback switch immediately detects the problem and switches over to the backup cable.

Fallback switches that can be managed using Simple Network Management Protocol (SNMP) management consoles are very useful. For example, you could use a remote SNMP terminal to cause a fallback switch to change from a primary to a secondary line if you need to take the primary line down for maintenance. Ganged fallback switches can be used to control multiple serial or local area network (LAN) devices simultaneously. For example, you could schedule a ganged switch to switch over from a set of primary Web servers to a backup Web server every night during a period of low traffic while maintenance or backups are performed on the primary servers. Be sure to use a fallback switch with some form of password protection on its SNMP management functions.

Examples

An example of a resource requiring high availability is a high-speed T1 line that is used by remote clients for accessing a corporate intranet. If the primary T1 line goes down, there must be a backup line that provides instant, transparent failover support for clients. The solution is to use two T1 lines connected to a fallback switch by a serial interface such as RS-232 or V.35. The fallback switch detects a failure the moment the primary line goes down and can perform a remedial action such as

- Automatically switching over to the backup line
- Sounding an audible alarm to notify administrators
- Generating an alert to an SNMP management console

Fast Ethernet

A set of Ethernet standards for 100-megabit-per-second (Mbps) data transmission.

Overview

Ratified as the IEEE 802.3u specification in 1995, Fast Ethernet is an evolution of regular 10 Mbps Ethernet that transmits data at 10 times the speed of standard Ethernet. Fast Ethernet uses the same contention-based media access control method (Carrier Sense Multiple Access with Collision Detection, or CSMA/CD) and the same framing format as standard Ethernet. It also runs over the same structured wiring systems as well, including twisted pair and fiber-optic cabling, with the exception that there is no shared media (physical bus) cabling option as in 10Base2 and 10Base5 Ethernet.

Fast Ethernet is actually a group of standards collectively known as 100BaseT. Like the various 10 Mbps forms of Ethernet, Fast Ethernet also comes in full- and half-duplex varieties and can be implemented as shared media using hubs or in switched networks.

Uses

Fast Ethernet is used mainly for switch uplinks and interconnects for high-speed backbones, switch connections to high-speed servers in server farms, and islands of high-performance workstations running bandwidth-intensive software such as computer-aided design (CAD) or multimedia applications.

Fast Ethernet switches can also be used for segmenting your network to reduce bottlenecks caused by users trying to access key servers on the network. Simply connect each 10/100 autosensing hub to a Fast Ethernet switch, and connect the servers directly to the switch.

Architecture

Fast Ethernet increases its speed tenfold over standard Ethernet by decreasing the bit time (the time duration of

each transmitted bit) by a factor of 10. This allows Fast Ethernet to maintain all of the main characteristics of 10 Mbps Ethernet and be compatible with 10 Mbps Ethernet to allow mixed networks of 10 and 100 Mbps segments to coexist. The Fast Ethernet specifications also include a mechanism for autonegotiation of frame speed called autosensing, which lets vendors build dual 10/100-Mbps hubs, switches, and bridges for easily incorporating Fast Ethernet into legacy 10 Mbps Ethernet networks.

Implementation

Fast Ethernet can be implemented in four different media (cabling) formats, which are collected under the umbrella designation of 100BaseT. These four formats are

- **100BaseTX:** This is the most popular implementation of Fast Ethernet. 100BaseTX uses two pairs of wires in Category 5 (Cat5) unshielded twisted-pair (UTP) cabling (the same cabling as the popular but lower-speed 10BaseT variety of Ethernet). 100BaseTX also supports w-pair shielded twisted-pair (STP) cabling as well, but this is rarely used and is available in both half-duplex and full-duplex signaling.
- **100BaseFX:** This form can use duplex (two-strand) 50 or 62.5 micron multimode fiber-optic cable or 9 micron single mode cabling, typically terminated with ST connectors. It is used mainly for backbone wiring such as switch-switch connections and is available in both half-duplex and full-duplex signaling.
- **100BaseT4:** This form uses all four pairs of wires in twisted-pair cabling and enables Fast Ethernet to be used over inexpensive Category 3 (Cat3) UTP cabling. 100BaseT4 supports half-duplex signaling only.
- **100BaseT2:** This form uses two pairs of wires in either Cat3, Category 4 (Cat4), or Cat5 UTP cabling and supports both half- and full-duplex signaling. This option was developed by the Institute of Electrical and Electronics Engineers (IEEE) but was never implemented in commercial Fast Ethernet equipment.

Two-port 10/100 Ethernet switch

Fast Ethernet. Fast Ethernet island connected to legacy 10BaseT network.

Repeaters (hubs) for Fast Ethernet networks come in two varieties:

- **Class I repeaters:** Perform internal signal translation that introduces slight propagation delays but allows different types of Fast Ethernet media, such as 100BaseTX and 100BaseFX, to be connected. You can use only one Class I repeater per Fast Ethernet segment.
- **Class II repeaters:** Take incoming signals and repeat them immediately (without translation) to all outgoing ports, thus minimizing port latency. Class II repeaters require that all ports connect to the same media, such as 100BaseTX. You can use up to two Class II repeaters per Fast Ethernet segment.

For 100BaseTX, attached stations cannot be more than 328 feet (100 meters) from a hub or repeater (same as 10BaseT) with the maximum network diameter being 690 feet (210 meters), compared to 1640 feet (500

meters) for 10BaseT. 100BaseFX supports longer distances up to 1.25 miles (2 kilometers). In reality, building Fast Ethernet networks is a trifle more complex because the distance limitations of different media options often depend on the class of repeaters used and whether station-hub or hub-hub connections are under consideration.

There are also nonstandard vendor-specific external transceivers available that allow Fast Ethernet to be extended over long-haul multimode fiber for distances as long as 62 miles (100 kilometers).

Advantages and Disadvantages

Switching to Fast Ethernet is probably the easiest and cheapest way of upgrading your network to meet increasing bandwidth needs. The advantages of upgrading 10 Mbps Ethernet networks to Fast Ethernet include the following:

- Fast Ethernet integrates easily into existing 10 Mbps Ethernet networks without requiring reinvestment in new network-management and troubleshooting software.
- Fast Ethernet is based on the same simple technology as standard 10 Mbps Ethernet, which makes equipment cheap and easy to produce and reduces the amount of training needed to implement it.
- Fast Ethernet can carry voice, data, and video at 100 Mbps, which is 10 times faster than traditional 10 Mbps Ethernet.
- Fast Ethernet can operate over the same installed media used for a traditional 10 Mbps Ethernet network.
- The network can be migrated slowly to Fast Ethernet by using autosensing 10/100 hubs and network interface cards (NICs).

These advantages have made Fast Ethernet the natural successor to standard 10 Mbps Ethernet and have led to the eclipse of competing high-speed networking technologies such as Fast Token Ring and Fiber Distributed Data Interface (FDDI).

Marketplace

The list of vendors offering Fast Ethernet equipment is too long to mention here. One example of the technology's popularity is that every version of Cisco Catalyst switch available supports Fast Ethernet.

Analysts estimate that more than 100 million Fast Ethernet ports were shipped in 2000, a figure that is expected to double by 2004. Price per port has dropped to below \$100, making Fast Ethernet an attractive and affordable option for small and mid-sized businesses that need to upgrade their networks. Despite the current market excitement over Gigabit Ethernet (GbE) and the predicted arrival of 10 GbE, Fast Ethernet is likely to remain the primary networking technology for corporate networks for at least the next five years.

Notes

An alternative to Fast Ethernet developed by Hewlett-Packard is 100VG-AnyLAN, also called 100BaseVG and standardized as IEEE 802.12. 100VG-AnyLAN is a 100 Mbps transmission technology that uses a media access control technology called demand priority that Hewlett-Packard originally developed for transporting both Ethernet and Token Ring frames. 100VG-AnyLAN is now considered a legacy technology compared to Fast Ethernet.

FAT

Stands for file allocation table; specifically, a table maintained on a hard disk by MS-DOS and Microsoft Windows operating systems that acts as a table of contents, showing where directories and files are stored on the disk. By extension, the acronym FAT is also used to refer to the file system itself for MS-DOS and Windows platforms.

See: *file allocation table (FAT)*

FAT32

An enhanced version of a file allocation table (FAT), supported by Microsoft Windows 95 OSR2, Windows 98, Windows Millennium Edition (Me), Windows 2000, Windows XP, and Windows .NET Server.

Overview

FAT32 theoretically supports drives of up to 2 terabytes (2048 gigabytes [GB]) in size, although for Windows 2000, Windows XP, and Windows .NET Server the actual size limit is 32 GB. If the installation partition is smaller than 2 GB, it will automatically be formatted using FAT. If the installation partition size is equal to or greater than 2 GB, it will automatically be formatted as FAT32.

FAT32 uses a smaller cluster size than FAT so is more efficient at utilizing disk space on large volumes (those greater than 512 megabytes [MB] in size) than FAT. The savings in disk space using FAT32 instead of FAT for large volumes is typically 20 to 30 percent. The following two tables show the difference in cluster sizes between the original FAT and FAT32.

FAT Cluster Sizes

<i>Drive Size</i>	<i>FAT Cluster Size</i>
0 MB–32 MB	512 bytes
33 MB–64 MB	1 kilobyte (KB)
65 MB–128 MB	2 KB
129 MB–256 MB	4 KB
257 MB–512 MB	8 KB
513 MB–1024 MB	16 KB
1025 MB–2048 MB	32 KB

FAT32 Cluster Sizes

<i>Drive Size</i>	<i>FAT32 Cluster Size</i>
260 MB–8 GB	4 KB
9 GB–16 GB	8 KB
17 GB–32 GB	16 KB
More than 32 GB	32 KB

Notes

Using FAT32 (or FAT) with the Windows 2000, Windows XP, and Windows .NET Server operating system platforms is not recommended because it does not offer the security features that are provided by the NTFS file system (NTFS). FAT32 also does not support

disk compression. The only time you'd use FAT32 with Windows 2000, Windows XP, or Windows .NET Server is in a dual-boot situation, which Microsoft Corporation does not recommend. Note that in a dual-boot system, FAT32 volumes cannot be accessed by any operating systems other than Windows 95 OSR2, Windows 98, Windows 2000, Windows XP, or Windows .NET Server. For dual-boot with Windows 95, Windows 98, or Windows NT, drive C must be a FAT partition.

Remember, a client that connects over the network to a shared folder in Windows 2000, Windows XP, or Windows .NET Server can access files in that folder regardless of whether the folder is stored on an NTFS, FAT, or FAT32 volume—provided the client has the appropriate permissions to do so.

See Also: *file allocation table (FAT), NTFS file system (NTFS)*

FAT volume

A partition on a physical disk formatted using the file allocation table (FAT) file system.

Overview

FAT volumes can be used to share folders for users to access over the network, but they lack the advanced security control and auditing features of NTFS file system (NTFS) volumes. The maximum file partition size is 4 gigabytes (GB) in Microsoft Windows NT and 2 GB in MS-DOS, Windows 3.x, Windows 95, and Windows 98. Windows 2000, Windows XP, and Windows .NET Server will actually format a partition as FAT32 if the partition is larger than 2 GB.

Notes

Be sure to regularly defragment heavily used FAT volumes because the FAT file system can easily become fragmented when files are deleted and created. Use FAT volumes instead of NTFS volumes when you want to dual-boot Windows NT, Windows 2000, Windows XP, or Windows .NET Server systems with earlier MS-DOS, Windows 3.x, Windows 95, or Windows 98 systems.

fault tolerance

Any mechanism or technology that allows a computer or operating system to recover from a failure.

Overview

In fault-tolerant systems, the data remains available when one component of the system fails. Here are some examples of fault-tolerant systems:

- Transactional log files that protect the Microsoft Windows registry and allow recovery of hives
- Redundant array of independent disks (RAID)-5 disk systems that protect against data loss
- Uninterruptible power supply (UPS) to protect the system against primary power failure

Notes

Just because your system is fault tolerant does not mean you are fully prepared for disaster. You still need to perform regular backups of important data. For example, a RAID-5 disk system will protect against data loss if one disk drive fails, but not if two or more drives fail simultaneously.

FDDI token passing

The token-passing access method for Fiber Distributed Data Interface (FDDI) networking.

Overview

The token-passing method used by FDDI is generally similar to the token-passing definition outlined in the IEEE 802.5 specification for Token Ring networks. However, in an FDDI ring, each host holds the token for a predetermined amount of time and can transmit as many frames as it can produce during this time. When the time interval expires, the host must release the token for the next host on the ring to use. This differs from the IEEE 802.5 specification in that many frames from each host can exist on the ring at the same time, instead of only one frame per host, as is the case in Token Ring networks. This allows FDDI networks to support higher data traffic rates than Token Ring networks and makes FDDI more suitable for network backbones.

Federal Communications Commission (FCC)

A U.S. government agency regulating all aspects of telecommunications.

Overview

The Federal Communications Commission (FCC) was established under the Communications Act of 1934 as an independent federal regulatory agency. Among other

responsibilities, the FCC licenses portions of the electromagnetic spectrum for communication technologies such as cellular phones and wireless networking. For example, in 1994 the FCC auctioned off portions of the 1900-megahertz (MHz) radio wave section of the electromagnetic spectrum to enable companies to deploy Personal Communications Services (PCS) technologies for cellular communication. FCC auctions are intended to increase the number of cellular phone providers in the United States, foster growth and competition in the telecommunications industry, and raise money for the U.S. government treasury.

One role of the FCC is to implement communication legislation passed by Congress. The Telecommunications Act of 1996 represents the first major overhaul of the laws regarding telecommunications in more than 60 years. The FCC is tasked with enforcing this legislation, which is designed to open up competition in the telecommunications arena to foster innovation and economic progress.

Federal Information Processing Standard (FIPS)

Any standard ratified by the National Institute of Standards and Technology (NIST).

Overview

NIST is a U.S. government organization responsible for developing standards in industry and commerce. Federal Information Processing Standard (FIPS) standards are one aspect of the work of NIST and represent standards relating to computing, networking, cryptography, and related subjects.

An example of a FIPS standard is FIPS-140, the “Security Requirements for Cryptographic Modules” standard whose compliance is required by the U.S. government by vendors developing hardware and software platforms for sensitive (but not classified) cryptographic purposes. Microsoft Windows 2000, Windows XP, and Windows .NET Server cryptographic services are FIPS 140-1 Level 1 compliant.

Notes

Another recent FIPS standard is the Advanced Encryption Standard (AES) that officially replaced the aging Data Encryption Standard (DES) in 2001.

Fiber Distributed Data Interface (FDDI)

A high-speed networking technology used mainly for campus backbones.

Overview

Fiber Distributed Data Interface (FDDI) was developed in the early 1980s as a high-speed networking technology for processor-to-processor communications. It was the first local area network/metropolitan area network (LAN/MAN) networking technology that could support data transmission speeds of 100 megabits per second (Mbps). (Until 1993, its only competitor was 16 Mbps Token Ring, a much slower technology.) Although developed originally for the host interconnection environment, FDDI quickly evolved into a popular technology for building high-speed distributed backbones for campus-wide networks and reached its peak of popularity in the mid-1990s.

FDDI transmits data at 100 Mbps over fiber-optic cabling (either single-mode or multimode) configured in a dual physical ring topology. The dual ring topology provides redundancy since the secondary ring is used as a standby for the primary ring. By utilizing the secondary ring for traffic instead of redundancy, FDDI is also capable of transporting data at 200 Mbps. There is also

a version of FDDI called Copper Distributed Data Interface (CDDI) that is implemented using copper cabling instead of fiber-optic cabling, but this is not as popular as the fiber version.

FDDI is standardized by the X3T9 committee of the American National Standards Institute (ANSI) and is an International Organization for Standardization (ISO) standard.

Architecture

FDDI uses a token-passing technology similar to that of Institute of Electrical and Electronics Engineers (IEEE) 802.5 Token Ring networks. FDDI stations generate a three-octet token that controls the sequence in which other stations will gain access to the wire. The token passes around the ring, moving from one node to the next. When a station wants to transmit information, it captures the token, transmits as many frames of information as it wants within the specified access period and releases the token (this feature of transmitting multiple data frames per token capture is known as a timed token or capacity allocation scheme and differentiates it from the priority mechanism used in IEEE 802.5 Token Ring). Each node on the ring checks each and every frame to see if it is the frame's intended recipient, and the recipient node reads the information from the frame. When a frame completes its travel around the ring and returns to its originating node, the frame is stripped from the ring.

FDDI is a connectionless networking architecture that supports both asynchronous and synchronous transmission. FDDI packages data in frames that use 48-bit addressing similar to MAC addressing for Ethernet. The frame size for an FDDI frame can range from 32 to 4400 bytes. FDDI frames can encapsulate local area network (LAN) traffic such as Internet Protocol (IP) packets for transmission over FDDI backbones. Different FDDI implementations use one of three possible framing formats:

- **FDDI-raw:** Supported by Cisco routers running Internetwork Operating System (IOS) versions 11.1.x and later, and by some third-party vendors
- **FDDI with LLC:** Supported by IOS versions 10.0 and earlier

- **FDDI with LLC and SNAP:** Default format for encapsulating Internetwork Packet Exchange (IPX) packets on FDDI

Implementation

FDDI is usually implemented as a dual token-passing ring that uses a physical and logical ring topology for campus-wide backbone networks or a physical ring but logical star topology for FDDI LANs within a building. An FDDI dual ring consists of a primary and secondary ring operating in a counter-rotating fashion. While the primary ring always carries data, the secondary ring is usually reserved as a backup in case the primary ring goes down. This scheme provides FDDI with the degree of fault tolerance valuable for mission-critical network backbones. In the event of a failure on the primary ring, FDDI automatically reconfigures itself to use the secondary ring, as shown in the illustration. Faults can be located and repaired using a fault isolation technique called beaconing.

FDDI can also be implemented in a form where the secondary ring also carries data, but in the opposite direction from the primary ring. This configuration extends the maximum potential bandwidth of FDDI to 200 Mbps.

Nodes (or stations) on an FDDI backbone can connect to either one or both rings depending on the media interface connector (MIC) employed. These nodes may be directly attached computer systems, concentrators (similar to Token Ring Multistation Access Units [MAUs]), or bridges and switches for connecting FDDI to other LAN/WAN architectures. The two ways of attaching nodes to an FDDI backbone are

- **Dual-Attached Stations (DAS):** Also called Class A stations, these devices connect to both rings using dual fiber-optic connectors. The A port is the point at which the primary ring enters and the secondary ring leaves, and the B port is the reverse. Dual-attached stations use both rings, with the secondary ring serving as a backup for the primary. Dual-attached FDDI is used primarily for network backbones that require fault tolerance. Single-attached stations can be connected to dual-attached FDDI backbones using a dual-attached device called a concentrator or multiplexer.

- Single-Attached Stations (SAS):** Also called Class B stations, these devices connect to either the primary or secondary ring using S ports. Single-attached FDDI uses only the primary ring and is not as commonly deployed for network backbones as dual-attached FDDI. Single-attached stations are used primarily to connect Ethernet LANs or individual servers to FDDI backbones.

FDDI supports up to 500 nodes in its normal dual-ring configuration with distances up to 1.25 miles (2 kilometers) between adjacent nodes. The maximum circumference for an FDDI ring is 62.5 miles (100 kilometers) (or 125 miles/200 kilometers for both rings combined), and there must be a repeater every 1.25 miles (2 kilometers) or less. Bridges or routers are used to connect the FDDI backbone network to Ethernet or Token Ring departmental LANs.

Prospects

In the late 1980s and early 1990s, FDDI was the most popular networking technology for building distributed high-speed campus backbones. Asynchronous Transfer Mode (ATM) was its only competition, but ATM's complexity resulted in slow adoption and relegation of this technology mainly to telecommunication carrier networks.

When Fast Ethernet emerged in 1993, it competed with FDDI with respect to speed but could not do so with respect to distance. Nevertheless, FDDI lost some ground to Fast Ethernet, mainly because Fast Ethernet could be deployed in a switched full-duplex form to build collapsed backbones, a new network backbone architecture that competed with FDDI's distributed backbone architecture. The result was that the market for FDDI technology peaked in 1995 and has been declining ever since.

With the emergence of Gigabit Ethernet (GbE) in 1997, however, the death knell for FDDI began to sound. Switched full-duplex GbE could replace legacy FDDI backbones in campus networks and provide speed increases of tenfold to better carry escalating network traffic.

A working FDDI backbone:

When a fault occurs in the primary ring:

Fiber Distributed Data Interface (FDDI). Fault-tolerant operation of dual-ring FDDI.

The final blow came in early 2001, when manufacturers of chips used in FDDI transceivers closed shop and stopped producing, which means that once the current

supply of vendor’s FDDI equipment is sold, no more will be manufactured. Because of these market developments, most large enterprises using FDDI have begun or already completed migrating their network backbones from FDDI to GbE. Although FDDI is a stable technology that has proved reliable in the enterprise, the impending unavailability of replacement equipment makes migration to GbE advisable.

Notes

When bridging between Ethernet LANs and FDDI backbones, be aware that there are two types of bridges:

- **Encapsulating bridges:** Encapsulate Ethernet frames into FDDI frames
- **Translating bridges:** Translate source and destination MAC addresses into FDDI addresses

Deploying these two FDDI bridging technologies together can result in incompatibilities. For example, although Cisco FDDI bridges can generally interoperate with translating bridges from other vendors, their encapsulation method is proprietary and usually will not work with encapsulating bridges from other vendors. Both types of bridging methods are commonly used in FDDI networks.

The following table shows some troubleshooting tips for FDDI networks.

FDDI Troubleshooting

Problem	Suggestions
FDDI ring is not functioning.	Check the status of the router’s FDDI interface, making sure the interface and line protocol are up. Try pinging a remote router. Check the physical connections of the cable; use an optical time domain reflectometer to test for problems.
Signal is degraded.	Check whether the upstream FDDI neighbor has failed and the bypass switch has been activated.

fiber exhaust

A term referring to the potential saturation of the fiber-optic backbone of the Internet due to the exponentially increasing demand for Internet services.

Overview

As high-speed residential Internet access using cable modems and Asymmetric Digital Subscriber Line (ADSL) technology becomes more and more widely deployed, this creates stress on the capacity of the Internet’s backbone for carrying all this additional traffic. Another factor contributing to fiber exhaust is the move within the corporate arena toward new high-bandwidth services such as Internet Protocol (IP) telephony and video multicasting technologies delivered over the Internet. Some analysts foresee conditions arising within the next few years that could cause significant degradation in the performance of the Internet due to the proliferation of these services.

Strategies that telecommunications carriers can use to prevent fiber exhaust from occurring include

- Creating additional high-speed, fiber-optic backbone lines for the Internet by laying down more fiber
- Using dense wavelength division multiplexing (DWDM) technologies to enable existing fiber backbones to carry additional traffic
- Upgrading existing time-division multiplexing (TDM) fiber backbones to higher bit rates

fiber-optic cabling

A glass cabling media that sends network signals using light.

Overview

Fiber-optic cabling (or simply fiber) is the main alternative to copper cabling for building wired computer networks (a network build using wires is called a wireline network, as opposed to a wireless network that transmits data using radio transceivers). Fiber-optic cabling has higher bandwidth capacity than copper cabling and is used mainly for high-speed networking such as Asynchronous Transfer Mode (ATM) and Gigabit Ethernet

(GbE) backbone networks, long cable runs between buildings, and switched connections to high-speed server farms and high-performance workstations.

Fiber-optic cabling. Composition of fiber-optic cabling.

As shown in the illustration, fiber-optic cabling consists of a glass core between 5 and 100 microns in diameter (for comparison, a sheet of paper is about 25 microns thick and a human hair about 75 microns thick). This glass core is the signal-carrying medium of the cable, and its extreme purity and transparency allow light to travel along it for many miles before being attenuated.

The glass core is surrounded by a thin layer of pure silica called cladding, which prevents light from escaping from the core by a process called total internal reflection. Surrounding the cladding are protective layers of acrylic plastic coating that give the cable stiffness to prevent it from being excessively bent (bending a fiber-optic cable too much can cause the glass core to fracture), Kevlar fibers for providing additional strength to resist stretching during installation, and a waterproof protective polyvinyl chloride (PVC) jacket that is usually colored a distinctive orange.

Fiber optic-capable networking components such as network interface cards, bridges, switches, and routers convert electrical signals into light pulses for transmission over fiber-optic cables. These light pulses are generated using either light-emitting diode (LED) or laser-emitting diodes and associated electronic circuitry.

The bandwidth of a fiber-optic cable depends on the distance (length of the cable) as well as the frequency used for transmitting the signal. Fiber bandwidth is usually expressed in frequency-distance form—for example, in megahertz-kilometers, or MHz-km. In other words, a 500-MHz-km fiber-optic cable can transmit a signal a distance of 5 kilometers at a frequency of 100 MHz ($5 \times 100 = 500$), or a distance of 50 kilometers at a frequency of 10 MHz ($50 \times 10 = 500$). In other words, there is an inverse relationship between frequency and distance for transmission over fiber-optic cables—the higher the frequency, the shorter the distance supported.

Uses

Fiber-optic cabling is often used for campus-wide backbones, long cabling runs between buildings, and local area network (LAN) connections to heavily used servers or high-speed workstations. Fiber is still not used extensively at the LAN level because it is more expensive and more difficult to install than copper cabling, but the gain in capacity to support future network upgrades often compensates for the increased installation costs.

Fiber-optic cabling. Connecting two local area networks (LANs) using fiber-optic cabling.

Multimode fiber of 62.5 micron diameter is the main type of fiber used for GbE networking. This is because 62.5 micron multimode fiber is also the standard for widely deployed 10BaseF Ethernet and 100BaseFX Fast Ethernet (and also FDDI) networks. This type of fiber supports distances up to 1800 feet (550 meters), making it suitable for building GbE backbones within buildings. If gigabit transmission over longer distances is required, 50 micron multimode fiber can be used instead, but this reduces flexibility since this type cannot be used for slower Ethernet networks. For really long GbE fiber connections, such as between buildings on a campus or across a metropolitan area network (MAN), single-mode fiber must be used.

Fiber is used also in heavy industrial environments where machinery can cause high levels of electromagnetic interference (EMI). Long-distance telecommunications carriers such as Sprint Corporation, MCI Worldcom, and AT&T also use fiber-optic cabling extensively for their long-haul (long-distance) telecommunications trunk lines.

Different styles of fiber-optic cabling exist, depending on the intended use. Examples include the following:

- **Duplex multimode cable:** With 62.5-micron core and 125-micron cladding, this is the most common general purpose cable type for most networking environments that require fiber-optic cabling. These cables usually come already terminated with pairs of connectors attached at each end, but you can also buy the cabling in bulk form where you can separate the two cables for termination purposes just as you can with an appliance power cord.
- **Breakout style cable:** This style of cabling contains multiple individual simplex fibers that are stranded around a central strengthening member. It is used for work-area connections and does not require patch panels.
- **Distribution style cable:** This style of cabling contains multiple individual simplex color-coded fibers that are stranded around a central strengthening member. It is often used in backbone applications that require multiple fiber connections.
- **Steel-reinforced cable:** This type of cabling uses a corrugated steel inner tube for protecting cable that needs to be buried or run outdoors.

Fiber-optic cabling is also available for purchase in bulk for those who want the challenge of terminating it themselves, but most customers buy standard or custom pre-terminated cables from suppliers. These cables can be simplex or duplex; they can be single-mode or multimode (multimode is most common); and they can be terminated with ST-ST, ST-SC, SC-SC, or SMA connectors.

Implementation

There are two basic types of fiber-optic cabling:

- **Single-mode fiber-optic cabling:** Has a narrow core (typically 7.1, 8.5, or 9 microns in diameter) that allows only one signal (light beam) to be sent or received at a time. Single-mode fiber-optic cabling uses laser-emitting diodes operating at frequencies between 1270 and 1355 nanometers (in the infrared range) to transmit signals over distances up to about 30 miles (50 kilometers) before dispersion will distort signals. Single-mode fiber is therefore ideal for long cable runs (up to 50 times farther than for multimode fiber-optic cabling).
- **Multimode fiber-optic cabling:** Has a thicker core (50, 62.5, or 100 microns in diameter) with sufficient width to allow multiple signals (light beams) to be transmitted simultaneously with each signal following a different path or mode through the fiber. Light-emitting diodes are used to transmit signals operating at frequencies between 770 and 860 nanometers (the near infrared) over distances up to about 3000 feet (900 meters) (longer cable runs can distort signals through modal dispersion). The thicker the glass core, the shorter the distance signals can be carried over the cable before dispersion causes signals to be degraded.

There are also two different types of multimode fiber:

- **Step-index multimode fiber:** The less costly variety of multimode fiber, it uses a wide core with a uniform index of refraction, causing the light beams to reflect in mirror fashion off the core's inside surface by the process of total internal reflection.

Because light can take many different paths down the cable and each path takes a different amount of time, signal distortion can result when step-index fiber is used for long cable runs, so use this type only for short cable runs.

- **Graded-index multimode fiber:** The more expensive type of multimode fiber, it uses a core made of multiple concentric layers of glass, each having a lower index of refraction than the layer it contains. In graded-index fiber, light beams follow curved paths and all rays reach the end of the fiber simultaneously, reducing the signal distortion that occurs in step-index fiber when long cable runs are used.

Connectors for fiber-optic cabling come in several varieties, including SC, ST, and SMA connectors. ST connectors have a wider installed base, but SC connectors are more versatile and more popular and are used in 100BaseFX, GbE, and Fibre Channel deployments. SMA connectors are sometimes used but do not conform to Electronic Industries Association/Telecommunication Industry Association (EIA/TIA) wiring standards. A newer type of connector is the MT-RJ, which has a snap latch fastener similar to an RJ-45 plug to simplify reconfiguring fiber networks from patch panels. Other connectors have appeared on the horizon for special purpose usage, but how popular these will become remains to be seen.

All forms of networking components are available in fiber-capable forms, including network cards, hubs, bridges, switches, and routers. Also available are line drivers, devices that enable you to extend or interconnect LANs in either point-to-point or multipoint configurations. Line drivers for fiber-optic cabling are available for synchronous or asynchronous transmission as well as for single-mode or multimode fiber.

Advantages and Disadvantages

Fiber-optic cabling has many advantages over copper cabling, including the following:

- Data transmission rates of up to 100 gigabits per second (Gbps) and higher are supported (copper transmission currently maxes out around 5 Gbps).

- Bit error rate (BER) for fiber is about 10^{-10} compared to 10^{-6} for copper, making fiber a much more reliable transmission media than copper.
- Low attenuation, allowing signals to be sent over distances measured in miles instead of feet.
- Less than 10 percent the weight of equivalent copper cabling.
- Immunity to crosstalk and noise caused by electromagnetic interference (EMI).
- Prevention of ground loops by electronically isolating transmitting and receiving stations.
- Greater signal security because signals cannot be picked up by electromagnetic induction as they can from copper cabling. Fiber must be tapped (physically opened) in order to eavesdrop on the transmission.

Prospects

Although copper has sufficed in many instances as LAN speeds have increased from 10 Mbps standard Ethernet to 1 Gbps GbE, it is not likely to be able to support speeds beyond 4 to 5 Gbps. The impending 10 GbE specification will likely be a fiber-only specification, and as a result, copper will probably be considered legacy technology in 5 to 10 years.

Although many have argued that fiber is prohibitively expensive for workgroup LAN deployments, recent case studies have suggested that this is not the case. The cost of laying fiber in a structured wiring scenario is only 10 to 20 percent higher than laying copper, and fiber network interface cards (NICs) for PCs are nearing prices of equivalent RJ-45 NICs. In structured wiring, however, laying fiber everywhere allows you to eliminate the traditional wiring closet on each floor and connect floors directly through patch panels and vertical rises to the main equipment room. This means you need far fewer switches and routers in a fiber-based structured wiring deployment than in a copper one. For example, ComputerWorld magazine reported that when George Washington University wired their 80-building campus using fiber, only 11 wiring closets were needed compared with an estimated 160 that would have been required had copper been used. The savings in equipment costs for new

installations make fiber a logical choice over copper and also lay the groundwork for future upgrades when faster networking technologies become available. Enterprise network architects would do well to always seriously consider using fiber for both new deployments and when networks are being upgraded.

Another impetus toward the long-awaited goal of fiber to the desktop is technological improvements in fiber-optic cabling and connectors. Some new fiber-optic cabling is so flexible that it can be tied in a knot without fracturing the core, making installation simpler and less worrisome. New and simpler connectors such as the LC connector from Lucent Technologies, Fiber Jack from Panduit Corporation, and VF-45 from 3M Corporation, Corning, and Siemens make fiber installation and configuration a simple plug-and-play process, with some of these connectors rivaling RJ-45 in size.

Notes

Be careful not to stress fiber-optic cabling unduly during installation. The maximum acceptable bend radius is usually 10 times the diameter of the cable, or about 1.2 inches (3 centimeters). Use an optical time domain reflectometer (OTDR) to test for faults after installation. Loss of signal, or attenuation, in fiber-optic cables can be caused by absorption (no medium is completely transparent to light), cable microbending (especially in single-mode fiber if it is not installed correctly), connector loss because of poor splicing or poorly installed or misaligned connectors, or coupling loss at the transmitter or receiver.

For safety, never look down a fiber-optic cable connected to your network because the invisible laser light can injure your retinas. When splicing connectors onto fiber, be careful to avoid getting shards of glass in your eyes or on your hands—use double-sided tape to clean the connection and remove loose shards and always wear protective goggles.

fiber to the curb (FTTC)

The laying of fiber-optic cabling by telcos to the customer premises.

Overview

Fiber to the curb (FTTC) is viewed by telcos as the successor to the copper local loop and will allow high speed broadband voice, video, and data services to be delivered directly to the subscriber on all-fiber lines without requiring conversion to electrical signals for transmission over copper. FTTC is thus envisioned by telcos as the replacement for the aging Plain Old Telephone System (POTS).

Other versions of the acronym include

- **FTTB:** Fiber to the building, used to describe commercial (as opposed to residential) upgrades of the copper local loop.
- **FTTN:** Fiber to the neighborhood, used to describe laying fiber from the telco central office (CO) to distribution boxes in neighborhoods.

Prospects

FTTC has been talked about by telcos for years, but it has not been deployed much for two reasons:

- The cost of building an entirely new cabling system to replace the existing copper one is extremely high.
- Technologies such as Asymmetric Digital Subscriber Line (ADSL) have allowed telcos to deliver high-speed data services and Internet connections to subscribers using existing copper local loop lines, and demand for ADSL has not yet been saturated.

A recent change in this situation is Project Pronto, an FTTN deployment underway by SBC Communications (a Regional Bell Operating Company [RBOC]). Project Pronto is designed to bring ADSL to areas that are currently too far away from COs for this to be possible, and it involves replacing copper subloops with fiber that runs directly from COs to remote terminals in distant neighborhoods. Some other RBOCs are also pursuing similar projects, so the era of FTTC may in fact be only a few years away, at least in metropolitan areas of the United States.

Fibre Channel

A high-speed networking technology mainly used for connecting storage devices to computer networks.

Overview

Fibre Channel is a gigabit networking technology developed in the late 1980s for connecting peripheral storage systems to mainframe hosts over long distances. The Fibre Channel specification was defined in 1994 by American National Standards Institute (ANSI) standard X3.230.

Fibre Channel typically provides data transfer at 1000 megabits per second (Mbps) or higher and is envisioned as the successor to Small Computer System Interface (SCSI) for connecting storage peripherals to computer systems and networks. Enterprise-level data storage technologies can benefit from Fibre Channel because the traditional SCSI interface has become a bottleneck in high-speed server-to-disk operations. Fibre Channel eliminates the limitations of bandwidth, distance, and scalability that are related to the SCSI standard and is becoming the industry standard for enterprise-level storage solutions involving high-performance redundant array of independent disks (RAID) arrays and storage area networks (SANs).

A simple Fibre Channel implementation could use a stackable hub or switch to connect a server or mainframe host to an external Fibre Channel RAID storage system using 100-Mbps redundant loops and hot-swappable disks. Servers can also use SCSI over Fibre Channel for connecting to legacy storage systems, and Fibre Channel can also carry Transmission Control Protocol/Internet Protocol (TCP/IP) and video traffic for server-to-server connections and high speed workstation connections in computer-aided design/computer-aided engineering (CAD/CAE) or multimedia environments.

Uses

Although Fibre Channel is viewed as the future replacement for the SCSI standard for connecting servers to external data storage units such as external hardware RAID arrays, it can also be used as a transport for high-speed data and video transmission over networks where Fibre Channel competes with other high-speed

networking technologies, such as Gigabit Ethernet (GbE) and Asynchronous Transfer Mode (ATM).

Architecture

Fibre Channel is built in a layered architecture that has five layers:

- **FC-0:** This is the lowest layer or physical interface and defines the optical and electrical characteristics and media options for deployment.
- **FC-1:** This layer is responsible for signal encoding and link control. Fibre Channel uses an 8B/10B encoding scheme that packages 8 bits of data into 10 symbols for transmission, which results in 25 percent protocol overhead (for example, 125 megahertz [MHz] signaling can only transmit data at 100 Mbps). Commands can be sent over a Fibre Channel network by prefixing them with a special character called K28.5.
- **FC-2:** This layer is responsible for framing, flow control, and class of service. Fibre Channel frames are 2,148 bytes long, of which 2,112 bytes constitute payload. Fibre Channel currently supports five different service classes, only three of which are commonly implemented, namely, Class 1 (circuit-switched), Class 2 (connectionless frame-switched), and Class 3 (connectionless point-to-multipoint).
- **FC-3:** This layer is open for specifying various advanced services that might be needed.
- **FC-4:** This is the top layer and is responsible for interoperability with other protocols such as Internet Protocol (IP) and SCSI-3.

Fibre Channel is a serial transmission scheme (like SCSI) and supports various transmission speeds, including 133 Mbps, 266 Mbps, 532 Mbps, and 1.0625 gigabits per second (Gbps). The last speed is most commonly used, and with 8B/10B line coding results in data rates of 100 megabytes (MBps), or 200 MBps in full duplex mode). There are plans to increase speeds to 4 Gbps as well.

Implementation

Despite its name, Fibre Channel can operate over both fiber-optic and copper cabling depending on how it is implemented, with fiber being the norm. Fiber links can be 6.2 miles (10 kilometers) or longer using single-mode fiber or up to 1640 feet (500 meters) on multi-mode fiber. Copper links are used mainly for short interconnects and are limited to 100 feet (30 meters) in length.

Fibre Channel. An example of using Fibre Channel to connect network storage systems to computer systems.

Fibre Channel signaling is performed by special transceivers. A Fibre Channel transceiver is more commonly known as a gigabit interface converter (GBIC), and GBICs can be found in Fibre Channel hubs, switches, and interface cards.

Fibre Channel can be deployed in three different network topologies:

- **Point-to-point:** This involves a dedicated link between only two devices such as two servers, a server and a disk storage system, a router/switch and a SAN, and so on.
- **Arbitrated loop:** This implementation, commonly called Fibre Channel Arbitrated Loop (FC-AL), uses a shared media approach to allow multiple devices to be connected together. It is the most common implementation method for Fibre Channel networks because of its flexibility and efficient use of bandwidth. A special process called arbitration determines which node has control of the media at any moment and is allowed to transmit. The logical topology is a daisy-chained system of loops similar to Fiber Distributed Data Interface (FDDI) and Token Ring architectures, but the actual physical topology is more commonly a hierarchical system of hubs and switches similar to Ethernet. Arbitrated loops can support hundreds of attached devices, but the more devices there are the less average bandwidth available to each device.
- **Switched fabric:** This involves using Fibre Channel switches to provide 100 Mbps switched connections to all connected devices through virtual point-to-point connections. Fully meshed topologies are supported for complete redundancy, and any number of devices can be connected to the fabric. Switched fabrics can theoretically support up to 15 million attached devices (unique addresses), but in practice the limit is about 1000. A downside of this approach is the additional latency caused by the need for virtual connections to be established and torn down frequently.

Advantages and Disadvantages

Fibre Channel's strengths include its protocol-independent transport service (in contrast to GbE's frame format, which extends from the desktop to the network backbone) and its guaranteed delivery service (included in Class 4 Fibre Channel, which makes it competitive with ATM's Quality of Service features). Also, although GbE is limited to general networking transport solutions and ATM is limited to networking and video transport, Fibre Channel can carry both network and

video traffic, connect computer systems and networks to network storage devices, and it can be used in high-performance clustering technology.

The main disadvantages are that Fibre Channel equipment is generally expensive, the technology is complex (compared to Ethernet), equipment from different vendors often suffers from interoperability problems, and native file sharing support is not provided.

Prospects

Interoperability issues between vendor implementations of Fibre Channel have been one factor slowing general adoption of the technology, but new specifications were released in 2000 to help make Fibre Channel equipment from different vendors work as simply as plug and play. The two most important of these new specifications are Direct Access File Specification (DAFS) and Fabric Shortest Path First (FSPF).

More seriously, Fibre Channel faces stiff competition from emerging new storage-over-IP network technologies including Service Specific Connection Oriented Protocol (SSCOP) from SAN Ltd., SCSI over TCP/IP from IBM and Cisco Systems, EtherStorage from Adaptec, and especially 10 GbE. This is somewhat ironic as the underlying physical layer technologies of GbE were in fact borrowed from the FC-0 and FC-1 layers of the earlier Fibre Channel standard!

These emerging storage-over-IP technologies promise several advantages over Fibre Channel, including more familiar underlying technology (Ethernet), better latency, lower packet loss, and transmission over longer distances. The industry debate is sometimes hot, from Fibre Channel proponents envisioning Fibre Channel being used for general local area network (LAN) transport to 10 GbE proponents declaring Fibre Channel as dead as FDDI.

But things are constantly changing in the networking world, and Fibre Channel may be down but not out. A new contender in the arena is Fibre Channel Over IP (FCOP), a scheme proposed by Lucent Technologies and other vendors. FCOP encapsulates Fibre Channel frames in IP packets to allow them to be carried over GbE or even long-haul ATM/Synchronous Optical Network (SONET) trunk lines, making FCOP a technology that could extend

Fibre Channel links to transcontinental distances. Using FCOP, for example, a SAN in New York can be connected to a corporate network in California over an ATM/SONET wide area network (WAN) link. A similar standard called Fibre Channel Backbone has also been proposed as a possible ANSI standard. We will have to wait until the dust clears on this one!

file

Information assigned a name and stored on a disk or some other media.

Overview

Files are the primary unit of information stored on disk systems. Examples of files include

- Executable files (programs)
- Data files (documents, databases)
- Web pages (HTML files)

Files are generally stored in a file system, which provides a hierarchical way of saving, locating, and accessing information.

file allocation table (FAT)

Specifically, a table maintained on a hard disk by MS-DOS and Microsoft Windows operating systems that acts as a table of contents, showing where directories and files are stored on the disk. By extension, the acronym FAT is also used to refer to the file system itself for MS-DOS and Windows platforms.

Overview

On Microsoft operating system platforms, when we refer to the file allocation table (FAT) file system, we often simply call it the FAT. The FAT is widely supported by all Windows platforms and can be

installed on partitions of up to 2 gigabytes (GB) in size on Windows 95 and Windows 98, and on partitions of up to 4 GB on Windows NT. In Windows 2000, Windows XP, and Windows .NET Server, if the partition size is greater than 2 GB, it will automatically be formatted as FAT32. The FAT is often used in dual-boot scenarios or when the security and reliability of the NTFS file system (NTFS) is not required.

The FAT file system is based on the FAT, a structure that maps the locations of the clusters in which files and folders are stored on the disk. The FAT records the location of each cluster that makes up a given file and the sequence in which it is stored. This is necessary because files usually are not stored in a contiguous location on a hard disk because of the presence of disk fragmentation caused by the creation and deletion of files on the disk. For each file on a FAT volume, the FAT contains the entry point for the allocation unit in which the first segment of the file is stored, followed by a series of links called the allocation chain. The allocation chain indicates where succeeding segments of the file are located and is then terminated by an end-of-file (EOF) marker.

Two copies of the FAT are kept in fixed locations on the disk to provide redundancy. A disk formatted with the FAT file system is said to be a FAT volume. The sizes of the individual clusters in which file information is stored on a FAT volume depend on the size of the partition or logical drive formatted using FAT, as shown in the following table. For compatibility reasons, these cluster sizes are the same whether the FAT volume is on an MS-DOS or Windows platform. In the table, you will see that on small FAT partitions (under 15 megabytes [MB] in size) a special 12-bit FAT file system is used instead of the usual 16-bit FAT.

FAT Information for Different Volume Sizes

<i>Drive Size</i>	<i>FAT Type</i>	<i>Sectors/ Cluster</i>	<i>Cluster Size</i>
0 MB–15 MB	12-bit	8	4 kilobytes (KB)
16 MB–127 MB	16-bit	4	2 KB
128 MB–255 MB	16-bit	8	4 KB
256 MB–511 MB	16-bit	16	8 KB
512 MB–1023 MB	16-bit	32	16 KB
1024 MB–2047 MB	16-bit	64	32 KB
2048 MB–4095 MB	16-bit	128	64 KB

Different versions of Windows support different file systems. The original release of Windows 95 supports only FAT, but Windows 95 OSR2 and Windows 98 support FAT and FAT32. FAT32 is a newer 32-bit version of FAT that was first included with the OSR2 release of Windows 95. The original version of FAT is 16-bit and is sometimes referred to as FAT16. Windows NT supports both FAT and NTFS, but not FAT32. Windows 2000, Windows XP, and Windows .NET Server support FAT, FAT32, and NTFS. Possible advantages of using FAT volumes with Windows NT, Windows 2000, Windows XP, and Windows .NET Server include the following:

- **Multiboot capability:** If you need to dual boot between Windows 95 or Windows 98 and Windows NT, use FAT instead of NTFS because Windows 95 and Windows 98 cannot read or recognize NTFS volumes.
- **Efficiency on small partitions:** FAT requires less overhead than NTFS and is more efficient on smaller volumes (those under 400 MB in size).

Notes

The root directory on a FAT volume has a fixed size and can contain only a limited number of entries.

File and Printer Sharing for Microsoft Networks

A Microsoft Windows networking component that allows computers running Windows to share folders and printers so that other clients can access them.

Overview

File and Printer Sharing for Microsoft Networks uses the Server Message Block (SMB) file sharing protocol and is compatible with clients such as

- Computers running Windows have Client for Microsoft Networks installed
- Windows NT, Windows 2000, Windows XP, and Windows .NET Server
- Windows for Workgroups
- LAN Manager

Use the Network utility in Control Panel to install Client for Microsoft Networks on a computer running Windows 95 or Windows 98.

Notes

You cannot install File and Printer Sharing for Microsoft Networks if File and Printer Sharing for NetWare Networks is already installed.

See Also: *File and Printer Sharing for NetWare Networks*

File and Printer Sharing for NetWare Networks

A Microsoft Windows networking component that allows computers running Windows to share folders and printers so that they can be accessed by Novell NetWare clients and by computers running Windows with Client for NetWare Networks.

Overview

Use the Network utility in Control Panel to install File and Printer Sharing for NetWare Networks on most versions of Windows. Installing File and Printer Sharing for NetWare Networks automatically installs the NWLink Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX)-Compatible Transport protocol and Client for NetWare Networks, if these have not already been installed. A bindery-based NetWare server must also be available as a network security provider because File and Printer Sharing for NetWare Networks does not support NetWare servers running Novell Directory Services (NDS).

Notes

You cannot install File and Printer Sharing for NetWare Networks if File and Printer Sharing for Microsoft Networks is already installed.

File and Print Services for Macintosh (FSM)

A Microsoft Windows 2000 service that provides Apple Macintosh users with access to files stored on NTFS file system (NTFS) volumes on Windows 2000 file servers.

Overview

File and Print Services for Macintosh (FSM) is the Windows 2000 counterpart to Services for Macintosh on machines running Windows NT. FSM lets PC and Apple Macintosh clients share files and printers. With FSM on a server running Windows 2000, Macintosh client machines need nothing more than the Macintosh operating system software installed to access resources on the server.

FSM integrates the following three services:

- **File Services for Macintosh:** Also called MacFile, this service lets Macintosh clients access files stored on the server running Windows 2000. Use MacFile to specify a directory on an NTFS volume as a Macintosh-accessible volume.
- **Print Services for Macintosh:** This service lets Macintosh clients print to printers connected to the server running Windows 2000 and spools print jobs for AppleTalk printers such as the LaserWriter.
- **AppleTalk protocol:** This service can be installed on the server running Windows 2000 to enable it to function as an AppleTalk router.

Once FSM is installed on your server, you can make directories available as Macintosh volumes by using the Shared Folders node in the System Tools folder of the Computer Management tool.

Notes

You can install an optional authentication module for Macintosh clients so that they can securely log on to Windows 2000-based servers running FSM.

File and Print Services for NetWare (FPNW)

A Microsoft Windows NT and Windows 2000 add-on utility for providing Internetwork Packet Exchange (IPX) file and print services to NetWare clients.

Overview

File and Print Services for NetWare (FPNW) enables a server running Windows NT or Windows 2000 to perform the following functions:

- Allow legacy NetWare 3.x IPX client machines to access resources on a server running Microsoft Windows NT
- Share directories and printers on a server running Windows NT so that NetWare 3.x clients can access them
- Manage NetWare 3.x printers from a server running Windows NT, making these printers also available to Microsoft clients

File and Print Services for NetWare (FPNW). How FPNW works.

Implementation

FPNW accomplishes these functions by mimicking the functionality of a NetWare 3.12 file and print server and providing file and print services directly to NetWare and compatible client computers. A server running Windows NT or Windows 2000 using FPNW appears to NetWare client machines as if it were really a NetWare server, and clients can access volumes, files, and printers just as they would on a NetWare server. Accounts for NetWare client users are stored in the Security

Accounts Manager (SAM) database, instead of requiring maintenance in a separate NetWare server. The FPNW server supports both the Server Message Block (SMB) protocol for Windows client connections and the NetWare Core Protocol (NCP) for NetWare client connections. FPNW requires that the NWLink IPX/SPX-Compatible Transport protocol be installed on the server.

FPNW supports NetWare functions such as user-account creation, remote administration, secure logins, and print queue management. However, it does not support NetWare functions such as user disk volume restrictions or inherited rights masks.

Notes

FPNW is not included with Windows NT or Windows 2000, but you can obtain it as a separate utility from your Microsoft value-added reseller (VAR). FPNW can be installed only on server machines, not on workstations. The directory that will be used as a NetWare SYS volume should be on an NTFS file system (NTFS) partition.

file extension

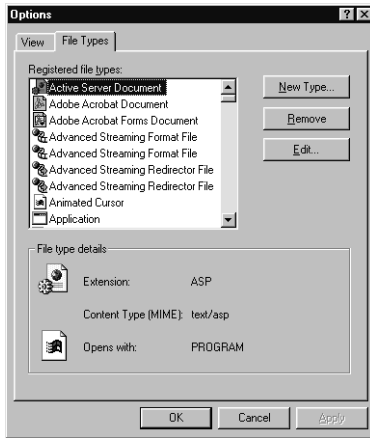

In Microsoft operating systems, a string appended to a filename, consisting of a period followed by three alphanumeric characters.

Overview

File extensions usually identify the application that can open or run them. For example, text files end with the extension .txt and are opened with Microsoft Notepad. Other common file extensions include the following:

- .doc for Microsoft Word documents
- .exe for executable files
- .htm for Web pages created in Hypertext Markup Language (HTML)
- .gif for GIF 87/89 format images, commonly used on the Internet

File extension. Viewing file extension mappings.

Associations between different file extensions and the programs used to open them are stored in the registry. Sometimes you might need to modify or remove a registered file extension. For example, if two different applications save files using the same file extension, you can easily modify file extensions in Microsoft Windows by using Windows Explorer. Just select Options from the View menu to open the Options dialog box, and select the File Types dialog box. Create, remove, or edit file extensions as desired. Be aware that using this tool might negatively affect the ability of applications on your system to function, so modify extensions with care. In Windows 2000, Windows XP, and Windows .NET Server, you can do the same by selecting Folder Options from the Tools menu.

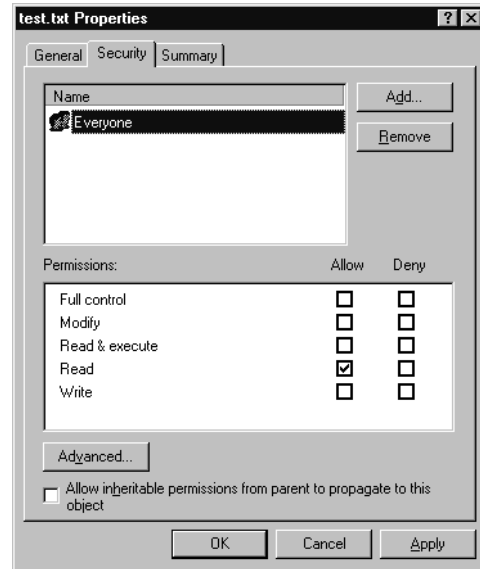

file permissions

A method for controlling access to files stored on NTFS file system (NTFS) volumes in systems running Microsoft Windows 2000 and Windows XP.

Overview

File permissions govern access to files on an NTFS volume, and folder permissions govern access to folders on an NTFS volume. There are five standard file

permissions on NTFS volumes for computers running Windows 2000, Windows XP, and Windows .NET Server: Full Control, Modify, Read & Execute, Read, and Write. For any given file on an NTFS volume, each of these file permissions can be allowed or denied for a specific user or group by using the Security tab of the file's property sheet in Windows Explorer (see the illustration).

File permissions. Viewing and configuring file permissions in Windows 2000.

Each of these five standard file permissions is made up of a subset of the individual or special file permissions that are available on NTFS volumes on machines running Windows 2000, Windows XP, and Windows .NET Server. The following table lists the various special file permissions and how they are combined to form the five different standard file permissions.

Special File Permissions

file system

Any technology for organizing, storing, and locating data on a system or network.

Overview

The file system for a computing platform defines the method by which the operating system stores, locates, and accesses files on its hard disk subsystem. File systems usually have a hierarchical structure consisting of a series of nested directories for storing files. Each directory can contain files, other subdirectories, or both. The top of the file system is called the root, and the various directories are its branches. The file system thus forms a tree.

File systems include conventions for the type and the maximum number of characters that can be used to name a file. A file can be located in the file system by specifying its absolute path—that is, its path starting from the root and traversing through the directory structure until the file is reached. Using graphical user interface (GUI) or command-line tools, files can be located, copied, moved, and deleted. Microsoft Windows Explorer is an example of a GUI tool that shows the hierarchical structure of the file system on a

Windows-based machine. File systems can incorporate technologies for marking files with attributes such as hidden and read-only. Some file systems allow you to compress files, and some allow you to specify file system quotas for users.

File system. A hierarchical file system.

Types

File systems can generally be classified into two types, depending on where the stored resources are located:

- **Local file systems:** These systems are part of the operating system and manage locally attached storage devices such as disk drives and removable drives. Portions of local file systems can be shared to allow users on the network to access specific files, but users generally need to know the name or location of the share in order to access it.
- **Distributed file systems:** These systems are used to combine shared portions of local file systems on many different machines into a single network-wide hierarchical file system. Distributed file systems allow shared network resources located all over the network to appear as though they are located on a single “superserver,” and they simplify the process of users locating and accessing shared network resources.

Examples

Examples of common file systems include the following:

- The file allocation table (FAT) file system for MS-DOS-based and Windows-based computers
- The NTFS file system (NTFS) for Windows NT, Windows 2000, Windows XP, and Windows .NET Server
- The Distributed file system (Dfs) for Windows NT, Windows 2000, and Windows .NET Server
- The standard hierarchical UNIX file system
- Sun's distributed Network File System (NFS) for UNIX platforms

File-Transfer Access and Management (FTAM)

The Open Systems Interconnection (OSI) reference model counterpart of the Internet standard File Transfer Protocol (FTP).

Overview

The File-Transfer Access and Management (FTAM) protocol is an OSI application layer (Layer 7) protocol that specifies a standard mechanism for access and management of a distributed network file system. FTAM enables users to

- Access file stores both locally and remotely, making FTAM a distributed file access protocol more similar to Gopher in this regard than to FTP
- Integrate management of both local and remote file stores, including the ability to manipulate both files and their attributes
- Access file stores on different kinds of machines that have different types of file systems
- Transfer files both synchronously and asynchronously

The FTAM model defines the architecture of a hierarchical virtual file store in terms of file structure, file attributes, and the kinds of operations that can be performed on files and their attributes. The FTAM standard does not specify the actual user interface for file access

and management, simply the system's underlying architecture. Vendors are left free to create their own user interfaces to FTAM file systems or use existing interfaces for their vendor-specific file systems. Some third-party vendors have developed FTAM-based products for Microsoft Windows NT and other operating systems, but like many aspects of the OSI model, FTAM has not caught on the way Internet protocols such as FTP have, mainly because of its complexity.

File Transfer Protocol (FTP). How FTP works.

Overview

File Transfer Protocol (FTP) is one of the earliest Internet protocols, and it is still used for uploading and downloading files between clients and servers. An FTP client is an application that can issue FTP commands to

an FTP server, and an FTP server is a service or daemon running on a server that responds to FTP commands from a client. FTP commands can be used to change directories, change transfer modes between binary and ASCII, upload files, and download files.

Implementation

FTP uses TCP for reliable network communication by establishing a session before initiating data transfer. TCP port number 21 on the FTP server listens for connection attempts from an FTP client and is used as a control port for establishing a connection between the client and server, for allowing the client to send an FTP command to the server, and for returning the server's response to the command. Once a control connection has been established, the server opens port number 20 to form a new connection with the client for transferring the actual data during uploads and downloads.

Notes

Internet Information Services (IIS) supports virtual servers and virtual directories using FTP. You can view the status of open ports on IIS using the netstat command. If an FTP client has trouble accessing information on IIS, try changing the directory listing style for the FTP service on IIS. FTP supports only Basic Authentication or anonymous access for authentication schemes and does not support the more secure Microsoft Windows NT Challenge/Response Authentication method.

Find

A dialog box in Microsoft Windows 2000, Windows XP, and Windows .NET Server that lets you locate objects in Active Directory directory service.

Overview

The Find dialog box allows you to query the global catalog server for objects such as users, groups, computers, shared folders, printers, and other objects in Active Directory.

Find. Using Find in Active Directory Users And Computers.

To use the Find dialog box, open a console with the snap-in for Active Directory Users And Computers installed, right-click on a container or organizational unit, and select Find from the shortcut menu. Then specify what kinds of objects you want to search for within Active Directory, such as

- Users, contacts, and groups
- Computers
- Printers
- Shared folders
- Directory folders
- Routers
- Custom search

Next, specify whether you want to search the entire Active Directory, a particular domain, or a particular organizational unit (OU). Finally, specify the query parameters associated with the type of object you are looking for. For example, if you are looking for users, contacts, or groups, you can specify the name of the object, its description, or specific attributes of the object, such as home phone or e-mail address.

Notes

If you are performing a search based on an attribute of an object, you must specify a value for this attribute.

finger

A Transmission Control Protocol/Internet Protocol (TCP/IP) protocol and service for viewing information about a user.

Overview

For a user on the client machine to be able to “finger” someone using finger client software, the finger daemon (service) must be running on the remote system being queried. Then if you finger a user’s e-mail address, the result returned to you typically includes the user’s username, full name, whether and how long the user has been logged on, and other information depending on the configuration of the finger service you are querying.

Microsoft Corporation’s implementation of TCP/IP on Microsoft Windows 2000, Windows XP, and Windows .NET Server has finger client software but no finger service. In other words, you can run the finger client on a machine running Windows 2000, Windows XP, or Windows .NET Server that is connected to the Internet in order to obtain results from a UNIX server at an Internet service provider (ISP) running the finger daemon. For example, typing the command **finger jsmith@s12.microsoft.com** displays information about user Jeff Smith on a server called s12.microsoft.com.

If an ISP makes its finger daemon publicly available on the Internet, it is commonly referred to as a finger gateway.

Notes

Finger is more of a security risk than a useful service in most cases and is not widely implemented anymore. A related service that also is not used much these days is whois.

FIPS

Stands for Federal Information Processing Standard, any standard ratified by the National Institute of Standards and Technology (NIST)

See: *Federal Information Processing Standard (FIPS)*

firewall

Any system or device that allows safe network traffic to pass while restricting or denying unsafe traffic.

Overview

Firewalls are usually dedicated machines running at the gateway point between your local network and the outside world and are used to control who has access to your private corporate network from the outside—for example, over the Internet. More generally, a firewall is any system that controls communication between two networks. In today’s networking environment in which corporate networks are connected to the Internet—inviting hackers to attempt unauthorized access to valuable business information—a corporate firewall is essential.

A firewall is an essential component of a company’s security policy and is one of the primary means for enforcing that policy. A firewall acts as a kind of police officer to monitor, control, arrest, and incarcerate malicious traffic, logging all questionable traffic to allow the administrator to determine the cause or source of the attack.

Types

A corporate firewall can either be a dedicated machine such as a packet filtering router or a rack mountable firewall appliance or firewall software that the administrator must install on a dual-home hardened system. Both approaches are popular and each has its advantages and disadvantages.

A personal firewall is a firewall used to protect a single machine, typically a home user connected to the Internet using dial-up, Asymmetric Digital Subscriber Line (ADSL), or cable modem connections. The personal firewall marketplace has exploded in the last few years as broadband Internet access services have become

widely deployed. Personal firewalls are usually implemented as software to be installed on users' machines, but the first personal firewall that was offered in appliance form was Firebox from WatchGuard Technologies in 1997. Personal firewalls also come preinstalled on some ADSL and cable modem routers to protect home users and Small Office/Home Office (SOHO) networks.

An offshoot of personal firewalls is the agent-based firewall. Agent-based firewalls are installed on every machine on a network, but their configuration is managed remotely using policies configured on a central policy server. At the enterprise level, this scenario is called a distributed firewall, and it is becoming a popular approach to secure servers on a network. The advantage here is that servers can be protected not just from hackers on the Internet but also from malicious users inside the corporate network. The agent also serves as an extra level of protection if the regular network firewall has been compromised. Another name for this approach is host-resident firewall, since it involves moving firewall security from the network's perimeter to the hosts themselves, a process that scales much better as perimeter traffic increases.

A new type of firewall is a combination of virtual private networking (VPN) and firewall software. This combination can be used for different purposes from enabling mobile users to connect securely to a corporate intranet over the Internet (using VPN and firewall software installed on their laptops) to enabling e-commerce sites to provide their users with secure access to their services (using rack-mounted VPN/Firewall appliances). In general, the firewall software is placed in front of (nearer the Internet) than the VPN software to simplify configuration. The main problem with this combination is that the VPN slows down access through the firewall, so a method of implementing this combination that is growing more popular is using dedicated high-performance VPN/Firewall appliances.

Finally, a different approach to implementing firewalls is outsourcing your firewall services to a Managed Firewall Service Provider (MFSP). This is becoming a popular alternative for small to mid-sized companies that cannot afford to hire trained security experts to

configure, monitor, and maintain a firewall. Some analysts expect this segment of the market to grow to \$1.5 billion by the end of 2002.

Architecture

In its simplest form, a firewall is a router (or dual-homed computer with two network interface cards) that filters incoming network packets. This configuration is usually called a packet-filtering router. By comparing the source addresses of these packets with an access list specifying the firewall's security policy, the router determines whether to forward the packets to their intended destinations or stop them. The firewall can simply examine the Internet Protocol (IP) address or domain name from which the packet was sent and determine whether to allow or deny the traffic. To specify a list of IP addresses which the router will permit or deny, an access control list (ACL) or access list (AL) is configured on the router. The router can filter both inbound and outbound packets.

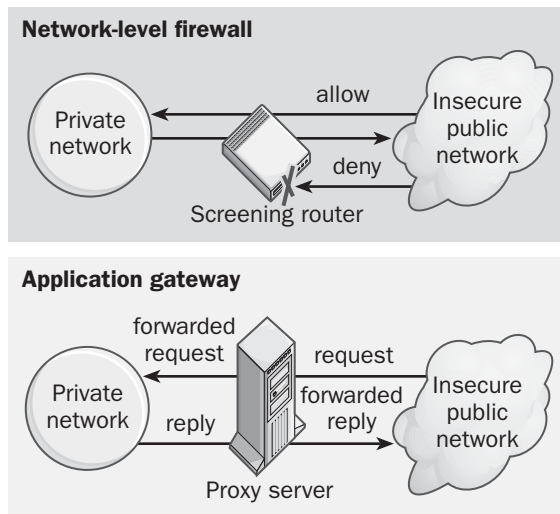

A related form of firewall is the network-level firewall because it operates at the network layer of the Open Systems Interconnection (OSI) reference model for networking. Network-level firewalls are transparent to users and use routing technology to determine which packets are allowed to pass and which will be denied access to the private network. Network-level routers can be configured to block certain types of IP traffic while permitting others to pass. Usually this is done by disabling or enabling different Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) ports on the firewall system. For example, TCP port 25 is usually left open to permit Simple Mail Transfer Protocol (SMTP) mail to travel between the private corporate network and the Internet, while other ports (such as port 23 for Telnet) might be disabled to prevent Internet users from accessing other services on corporate network servers. The difficulty with this approach is that the size of the access list for the firewall can become huge if a large number of domains or ports are blocked and a large number of exceptions are configured, and a large access list can slow down the router. Another difficulty is that some ports are dynamically assigned at random to certain services (such as remote procedure

call services) on startup, so it is more difficult to configure firewalls to control access to these ports using static access lists. Network-level firewalls are sometimes known as screening routers since they screen different types of traffic, and they are usually combined with packet-filtering using access lists for better security.

Routers that employ stateful filtering maintain an internal table of allowed TCP connections and only allow incoming connections to be established if they conform to this table. Stateful filtering is an alternative to access lists and is often used to control outbound traffic and reduce the size of access lists.

F

Firewall. Two basic types of firewalls.

Another type of firewall is the circuit-level gateway, which is usually implemented as part of a proxy server. Circuit-level gateways essentially operate at a higher level of the OSI model protocol stack than network-level firewalls do. With a circuit-level gateway, connections with the private network are hidden from the remote user. The remote user connects with the firewall, and the firewall forms a separate connection with the network resource being accessed after changing the IP address of the packets being transmitted in either direction through the firewall using a process called Network Address Translation (NAT). The result is a sort of

virtual circuit between the remote user and the network resource. This is a safer configuration than a packet-filtering router because the external user never sees the IP address of the internal network in the packets he or she receives, only the IP address of the firewall. A popular protocol for circuit-level gateways is the SOCKS v5 protocol. Circuit-layer gateways are typically used in conjunction with packet-filtering and network-layer protection.

Another more advanced type of firewall is the application gateway, which is also usually included in a proxy server. Application gateways do not allow any packets to pass directly between the two networks they connect. Instead, proxy applications running on the firewall computer forward requests to services on the private network and then forward responses to the originators on the unsecured public network. Application gateways generally authenticate a user's credentials before allowing access to the network, and they use auditing and logging mechanisms as part of their security policy. Application gateways generally require lots of configuration by users to enable their client machines to function properly, but they are more granular in their configurability than network-level firewalls. For example, if a File Transfer Protocol (FTP) proxy is configured on an application gateway, it can be configured to allow some FTP commands but deny others. You could also configure an SMTP proxy on an application gateway that would accept mail from the outside (without revealing internal e-mail addresses) and then forward the mail to the internal mail server. However, because of the additional processing overhead, application gateways have greater hardware requirements and are generally slower than other types of firewalls.

Other advanced features used by firewalls include

- **Execution control lists (ECLs):** These are like access lists but instead control which applications can be executed over the firewall.
- **Intrusion Detection Systems (IDSs):** Usually separate systems from firewalls but sometimes packaged with them, IDSs complement a regular firewall by allowing administrators not just to

prevent intrusion into their private networks but also to detect and analyze the source of this intrusion.

Implementation

Before looking at implementing firewalls, it is a good idea to first review some firewall terminology:

- **Host:** Any computer attached to your network.
- **Bastion host:** A host directly exposed to the Internet. Bastion hosts need to be “hardened” to make them more secure by removing nonessential services and software. Web servers and mail servers are two examples of common types of bastion hosts.
- **Perimeter network:** An extra network located between your corporate network and the Internet. Also called a DMZ, which stands for demilitarized zone.

The simplest way of implementing a firewall is to use a packet-filtering router with port screening at the junction between your private network and the Internet. All traffic flows through this point, and the router handles the entire job of securing your network from attack.

For more extensive protection than a simple packet-filtering router, install circuit-level or application-gateway firewall software on a dual-homed hardened system and use it in place of (or in addition to) the dedicated router.

A screened-host firewall allows a bastion host located on the private network to be accessed from the Internet while preventing other hosts from being compromised. This is perhaps less secure than locating the bastion host outside the private network, but it allows easier access to the bastion host for configuration and maintenance.

A screened subnet architecture employs an intermediate network (the perimeter network) between the private and public networks, each of which are connected to the perimeter network using a separate screening router. One or more bastion hosts are then located on the perimeter network. For greater protection, the perimeter network may be split into two segments using another router or a dual-homed host running firewall software.

Still another configuration makes each bastion host dual-homed, with one interface of each bastion host connected to the perimeter network segment adjacent to the Internet and the other interface connected to the perimeter network segment adjacent to the private network. You can make the topology even more complex by having separate perimeter networks for each bastion host, and so on.

Advantages and Disadvantages

Although firewalls are essential for networks connected to the Internet, a firewall is only as effective as its configuration. A misconfigured firewall is worse than no firewall at all since it provides the user with a false sense of security that the network is protected. In other words, firewalls cannot configure themselves and are only as smart as the administrators configuring them.

Another misconception is that a carefully configured firewall is all your network needs to be safe from attack. This is hardly the case. Network security begins with the development of a comprehensive security policy on paper and is implemented using a variety of systems and services including firewalls, perimeter networks, antivirus software, an intrusion detection system (IDS), and good network management practices. In addition, administrators need to be on top of possible new threats by subscribing to security newsletters, watching for notices of bugs and fixes from operating system and application vendors, reviewing firewall logs regularly, and educating users about the practices of safe computing.

Marketplace

For the corporate segment of the market, firewall products range from dedicated routers to software to install on hardened dual-homed hosts. A popular dedicated router firewall product is the PIX firewall service from Cisco Systems, included with IOS 11.2 and higher as the Cisco Firewall Feature Set. PIX comes in different flavors depending on whether the need is enterprise or Small Office/Home Office (SOHO) protection, and by some analysts' estimates is used by half of all large companies.

In the enterprise software firewall market, popular products include Firewall-1 from CheckPoint Software Technologies, Microsoft Proxy Server from Microsoft Corporation, and many others. The new Microsoft Internet Security and Acceleration (ISA) Server integrates firewall and Web caching functionality and supports policy-based security.

F

In the personal firewall arena, some popular products include BlackICE Defender from Network Ice Corporation, Norton Personal Firewall from Symantec Corporation, eSafe from Aladdin Networks, ZoneAlarm from Zone Labs, Secure Desktop from Sybergen Networks, McAfee Personal Firewall from Network Associates, CyberArmor from InfoExpress, and PC Firewall from ConSeal. In general, personal firewalls come with a standardized default configuration that provides a basic level of security, but remember that firewalls are only as smart as the person who configures them. Personal firewalls are also not a substitute for antivirus software and are usually ineffective in dealing with Trojan horses.

Distributed firewalls are popular in corporate environments and are typically used to protect critical servers using firewall agents that are remotely managed from a central policy server. Examples in this market include CyberArmor Enterprise Personal Firewall from Info Express and McAfee Active Virus Defense Suite from Network Associates.

Several vendors offer combinations of firewall and VPN software that can be used to provide secure remote access to corporate networks. Examples include VPN-1 Gateway (a combination of Firewall-1 and VPN-1) from CheckPoint Software, Raptor Firewall with PowerVPN from Symantec, GuardianPro with Guardian IPsec VPN from NetGuard, and eTrust Firewall with eTrust VPN from Computer Associates.

In the VPN/Firewall appliance arena, Cobalt Networks and Axent Technologies have teamed up to provide a 1U-high rack-mountable VPN/Firewall appliance called VelociRaptor that is based on the Linux operating system. Gigabit products in this market include Cisco's PIX 535 firewall and NetScreen-1000ES from NetScreen Technologies, both of which support Triple

DES encryption for greater security (although using 3DES slows down performance to about 600 megabits per second [Mbps]).

In the outsourced managed firewall services sector, two popular providers include DefendNet Solutions, whose DefendNet Enterprise solution uses CheckPoint Software's Firewall-1 product and targets companies with more than 250 users, and RIPTech, whose sentry monitoring system works with several popular firewalls including PIX, Raptor, and Firewall-1. Another managed firewall service provider is NetSolve.

Notes

TruSecure, in conjunction with ICSA Labs, acts as an independent standards body that certifies firewall products and provides a number of resources on their Web site relating to firewalls and network security. See www.icsalabs.com for more information.

The best way to begin configuring a packet-filtering firewall is to block all packets at first and then start allowing access to the internal network on a case-by-case basis. Make sure that internal network addresses do not cross the firewall to the outside world and do not store sensitive data on the machine running the firewall software itself. Treat your firewall machine as expendable—the worst possibility should be a hacker's damage to the firewall; this would simply leave your private network securely disconnected from the outside world. You can disable all unnecessary network services on your firewall machine to protect the firewall itself from attack.

If you are concerned only about controlling outgoing access from your network and your users do not need to be able to remotely access your network over the Internet, a packet-filtering router or circuit-level gateway type of firewall is probably sufficient. For users who frequently need to remotely access your network, however, an application gateway is generally best.

FireWire

A name trademarked by Apple Computer for the IEEE 1394 High Performance Serial Bus.

Overview

FireWire (or IEEE 1394 or simply 1394) is a serial transmission specification originally proposed by Apple for connecting high-speed peripherals to computers at speeds of up to 393 megabits per second (Mbps). FireWire supports hot-swapping of peripherals with up to 63 peripherals connected to a single FireWire bus. In addition, up to 1023 buses can be interconnected to form a vast array of peripherals if needed.

FireWire features simple plug-in connectors using thin serial cables that can be hot-plugged without interfering with your system's operation. FireWire connectors are based on the Nintendo Game Boy connector.

The main competitor for PC peripheral interconnection is Universal Serial Bus (USB). Although USB is targeted mainly toward computer peripherals running at speeds up to 12 Mbps, FireWire supports much higher speeds and can transport both asynchronous data and video streams and isochronous streams.

Other vendors have their own trademarked names for IEEE 1394, including Sony Corporation with its popular i.Link technology.

Implementation

FireWire as defined in IEEE 1394 uses 64-bit device addresses. FireWire cables use two twisted-pair wires for data transmission and two wires for power. FireWire includes two different serial interfaces:

- **Backplane interface:** Runs at speeds between 12.5, 25, and 50 Mbps for bus connections within a computer system
- **Point-to-point interface:** Runs at speeds of 98.304 Mbps (S100 specification), 196.608 Mbps (S200), and 393.216 Mbps (S400) for connecting devices to computers using serial cables

FireWire. Connecting peripherals using FireWire.

The topology of a typical FireWire implementation can be complex, but it is typically a hierarchical or tree topology consisting of various IEEE 1394 components. More complex topologies, including several computers sharing portions of the peripheral network, are also possible. The illustration shows how you can use FireWire. The four types of components you can use in a FireWire implementation are

- **Devices:** Typically have 3 ports but can have up to 27 ports and can be daisy-chained up to 16 devices
- **Splitters:** Provide extra IEEE 1394 ports if needed to accommodate the number and arrangement of devices used

- **Repeaters:** Overcome distance limitations in IEEE 1394 cables
- **Bridges:** Isolate traffic within a specific portion of an IEEE 1394 bus

FireWire connections have a maximum distance of 15 feet (4.5 meters), but up to 16 components can be daisy-chained to a maximum distance of 236 feet (72 meters) without using repeaters.

FireWire is supported by the Microsoft Windows 98, Windows 2000, and Windows XP operating systems, along with the universal serial bus (USB) specification.

Notes

Windows 98 resets the FireWire bus and assigns new physical addresses to IEEE 1394 devices when

- Devices are added or removed from the bus
- The system is rebooted

flapping

A problem condition that can occur with dynamic routers on large internetworks.

Overview

When a router is flapping (called a flapping router), it broadcasts routing table updates that alternate between two different routes to a host. For example, the flapping router might indicate during the first broadcast that route A is the best route to a given host, indicate during the second broadcast that route B is the best route, indicate during the following broadcast that route A is best, and so on. Flapping routers thus generate unnecessary routing traffic over the network. This generally happens when a router is unnecessarily configured to load balance between paths with equal hop counts. To determine whether a router is flapping, use a network packet sniffer.

flexible single-master operation (FSMO)

A unique set of single-master roles for domain controllers in Microsoft Windows 2000 and Windows .NET Server networks.

Overview

Although domain controllers in a Windows 2000 or Windows .NET Server network mainly function in multimaster mode in which all of them are peers, a few special domain controllers in an Active Directory directory service forest have special roles and execute these in single-master mode. These special roles are known as flexible single-master operation (FSMO) or “fismo” roles, and there are five of them:

- **Schema Operations Master:** There is only one of these domain controllers in the entire forest, and it is the only one that can be used to create new classes or attributes for the forest schema.
- **Domain Naming Master:** There is only one of these domain controllers in the entire forest, and it manages the names of every domain within the forest and is the only domain controller that can add or remove domains to the forest.
- **PDC Emulator or PDC Operations Master:** There is one of these domain controllers in each domain, and it is used to provide backward compatibility for downlevel Windows NT backup domain controllers (BDCs) within a mixed-mode network.
- **RID Master:** There is one of these in each domain, and it manages the assignment of domain-wide security IDs (SIDs).
- **Infrastructure Master:** There is one of these in each domain, and it updates the SIDs and distinguished names (DNs) in cross-domain references to objects.

flooding

Generally, a condition where a network is being bombarded by packets. In routing technologies, a method by which routers communicate to exchange routing table updates.

Overview

Flooding is a mechanism used by dynamic routers for exchanging routing table information with one another across an internetwork. When a router's routing table has changed, it typically floods the network with update messages to alert other routers to modify their tables too. This information is flooded so that every possible recipient router on the internetwork is notified.

The update packets broadcast by the first router are specially formed so that they are received by each subnet only once (otherwise the network could become truly flooded with such broadcasts and communications would be brought to a standstill).

flow control

The mechanism by which one asynchronous device controls the rate at which it receives data from another asynchronous device.

Overview

One common type of device where flow control is implemented is the modem, the most ubiquitous of asynchronous communications devices. Flow control is also used to describe data rate control mechanisms between other devices, such as computers and attached printers, or between Channel Service Unit/Data Service Units (CSU/DSUs) and routers.

Flow control. Different types of flow control between modems.

Flow control is sometimes equated with handshaking, but the term *handshaking* specifically refers to flow control negotiations that take place at the beginning of a communication session, although the term *flow control* also can apply to data transmission management during an active communication session.

In asynchronous communications technologies, two basic types of flow control exist:

- **Hardware flow control:** Also known as RTS/CTS (Request To Send/Clear To Send) control, this method uses special dedicated pinning on cables to leave flow control to the modem itself. In other words, a separate hard-wired signal link (wire) that does not carry data is used to enable one modem to send stop and start messages to the other modem by raising or lowering voltage levels on this wire. Hardware flow control is used with high-speed modems that can compress data and is usually the default setting for Microsoft Windows-based software, such as HyperTerminal, that uses modems.
- **Software flow control:** Also known as XON/XOFF control, this method uses special data characters (usually Ctrl+S to stop transmission, and Ctrl+Q to resume) sent within the data stream itself to enable a local modem to signal a remote modem to stop transmitting data so that the local modem can catch up.

Software flow control is slower and less reliable than hardware flow control because a user, program, or line noise might inadvertently generate a stop signal for the remote modem. In addition, software flow control is used only for transmitting ASCII text information, not for binary data files, because the binary data might contain the Ctrl+S stop character and cause the remote modem to stop transmitting data.

folder permissions

A method for controlling access to folders and their files stored on NTFS file system (NTFS) volumes in systems running Microsoft Windows 2000, Windows XP, or Windows .NET Server.

Overview

Folder permissions govern access to folders on an NTFS volume, and file permissions govern access to files on an NTFS volume. NTFS volumes for computers running Windows 2000, Windows XP, or Windows .NET Server have six standard folder permissions: Full Control, Modify, Read & Execute, List Folder Contents, Read, and Write.

F

Folder permissions. Configuring folder permissions in Windows 2000.

For any given folder on an NTFS volume, each of these folder permissions can be allowed or denied for a specific user or group by using the Security tab of the folder's property sheet in Windows Explorer (see the illustration).

Each of these six standard folder permissions is made up of a subset of the individual or special permissions that are available on NTFS volumes on machines running Windows 2000, Windows XP, or Windows .NET Server. The following table lists the various special permissions and how they are combined to form the six different folder permissions.

Special Folder Permissions

<i>Special Permissions</i>	<i>Full Control</i>	<i>Modify</i>	<i>Read & Execute</i>	<i>List Folder</i>	<i>Read</i>	<i>Write</i>
Traverse Folder	x	x	x	x		
List Folder	x	x	x	x	x	
Read Attributes	x	x	x	x	x	
Read Extended Attributes	x	x	x	x	x	
Create Files	x	x				x
Create Folders	x	x				x
Write Attributes	x	x				x
Write Extended Attributes	x	x				x
Delete Subfolders And Files	x					
Delete	x	x				
Read Permissions	x	x	x	x	x	
Change Permissions	x					
Take Ownership	x					

Notes

The List Folder Contents and the Read & Execute Folder permissions have the same special permissions. However, Read & Execute permission is inherited by both files and folders, but List Folder Contents permission is inherited only by folders.

foreign host

In a Microsoft implementation of Transmission Control Protocol/Internet Protocol (TCP/IP), any host that uses a non-Microsoft operating system.

Overview

Examples of foreign hosts on Microsoft IP internet-networks might be OS/2 workstations, Solaris servers, and VMS mainframes.

Connectivity with foreign hosts for the purpose of transferring files with the host requires

- A common networking protocol, such as TCP/IP or Internetwork Packet Exchange (IPX)

- A common file-sharing protocol, such as Server Message Block (SMB) or Network File System (NFS)

See Also: *Transmission Control Protocol/Internet Protocol (TCP/IP)*

foreign mail system

A mail system that belongs to a different company than your own and that might also be of a different type.

Overview

In Microsoft messaging terminology, the term *foreign mail system* usually refers to a mail system other than Microsoft Exchange Server. An example of a foreign mail system could be a public X.400 messaging system in Europe or the Internet's Simple Mail Transfer Protocol (SMTP) mail system. You can establish connectivity between an Exchange organization and a foreign mail system by installing and configuring an appropriate connector on an Exchange server in your organization. Examples include

- Using the Internet Mail Service to connect an Exchange organization to the SMTP mail system on the Internet
- Using the X.400 Connector to connect an Exchange organization to a public X.400 messaging network such as those common in Europe

forest

Also called a domain forest, a logical structure formed by combining two or more Microsoft Windows 2000 or Windows .NET Server Active Directory directory service trees. The trees within a forest are usually organized as peers and are connected by two-way transitive trust relationships that span across the root domains of each tree. All trees within a forest share a common schema and Global Catalog.

form

A feature of Hypertext Markup Language (HTML) that allows users to submit information to Web servers using Web browsers.

Overview

A form is a portion of a Web page that presents a series of fields for the Web browser user to complete, along with a Submit button to send the data to the Web server for processing. Forms are often used in Web sites for guest books, registration, and similar purposes. If you create an HTML form, you must create a corresponding form handler—an application that accepts the data from the form and processes it accordingly. Form handlers are typically written in Perl and implemented as Common Gateway Interface (CGI) scripts on UNIX Web server platforms such as Apache. On Internet Information Services (IIS), form handlers can be Internet Server API (ISAPI) applications written in C or Active Server Pages (ASP) scripts written in Microsoft Visual Basic, Scripting Edition (VBScript).

forwarder

A name server configured to perform iterative queries with other name servers on the Internet.

Overview

If one of your name servers is configured as a forwarder, all off-site queries for resolving Domain Name System (DNS) names are first sent to the forwarder. The forwarder then performs an iterative query with an off-site name server located at your Internet service provider (ISP) to resolve the query. The results of the query are cached by the forwarder. This caching of name query results by the forwarder speeds later name query requests and reduces traffic between your network and the ISP.

Forwarder. How a forwarder resolves a DNS name lookup.

Uses

Forwarders are useful for reducing name resolution traffic and speeding Domain Name System (DNS) name queries for large private Transmission Control Protocol/Internet Protocol (TCP/IP) internetworks that are connected to the Internet. They are also used to resolve name queries when a firewall between your network and the Internet prevents clients in your network from directly querying name servers located at your ISP or elsewhere on the Internet. In this case, a typical location for the forwarder is on the bastion host. (The bastion host is the host running the proxy server or application layer gateway application.)

FORTEZZA

A card-based system of cryptographic authentication.

Overview

FORTEZZA was developed by the National Security Agency (NSA) as a way of providing secure authentication to computer systems and services. FORTEZZA functions similarly to smart cards but has greater processing power and memory. The format for a FORTEZZA card is industry-standard Personal Computer Memory Card International Association (PCMCIA) interface, commonly used in laptop computers.

FORTEZZA cards are token-based authentication systems that are tamper-resistant and that protect the data stored on them using cryptography. FORTEZZA is

supported by Microsoft Internet Explorer in Microsoft Windows 2000 and Windows XP to control secure Web communications.

You can obtain FORTEZZA card systems from a variety of vendors approved by the NSA. One such vendor is Litronic, which offers a variety of FORTEZZA products and services.

FPNW

Stands for File and Print Services for NetWare, a Microsoft Windows NT and Windows 2000 add-on utility for providing Internetwork Packet Exchange (IPX) file and print services to NetWare clients.

See: File and Print Services for NetWare (FPNW)

FQDN

Stands for fully qualified domain name; in the Domain Name System (DNS), a dotted name that fully identifies a Transmission Control Protocol/Internet Protocol (TCP/IP) host on the Internet.

See: fully qualified domain name (FQDN)

fractional T1

A T-carrier digital circuit with a speed of less than 1.544 megabits per second (Mbps).

Overview

A fractional T1 line is a T1 line, leased by a T-carrier service provider to a customer, that carries only a fraction of the regular T1 bandwidth of 1.544 Mbps. Regular T1 lines consist of 24 DS0 channels multiplexed together, but fractional T1 lines consist of fewer than 24 channels. Fractional T1 lines typically consist of a combination of nailed-up channels and switched channels. The technology of fractional T-carrier services is the same as that of regular T-carrier services; the extra channels are simply unused. Customers might want to lease fractional T1 services when they do not require the entire bandwidth (or cost) of a regular T1 line.

FRAD

Stands for Frame Relay Access Device, a telecommunications device that enables a customer site to be connected to a telco's frame relay services.

See: Frame Relay Access Device (FRAD)

frame

A segment of data transmitted over a network or telecommunications link.

Overview

Frames are assembled and generated by the data-link layer and physical layer of the Open Systems Interconnection (OSI) reference model. This assembly process is called framing. In other words, packets from the network layer are encapsulated by the data-link layer into frames. Data segments generated by higher layers of the OSI model are generally referred to as packets, but the term *packet* is also sometimes used to include frames.

Architecture

A frame generally consists of a header with preamble (start of frame flag), destination and source addresses, data payload, and usually some form of error-checking information. Frames can be fixed-length or variable-length and have addressing information for multipoint connections or no addressing information for

point-to-point connections. They can also have error correction, as in X.25, or no error correction, as in frame relay.

The format in which data frames are constructed depends on the particular data-link layer protocol being used. Thus, we can speak of Ethernet frames, Integrated Services Digital Network (ISDN) frames, X.25 frames, frame relay frames, and so on. Each particular local area network (LAN) or wide area network (WAN) data-link protocol has its own method of framing data for transmission over the network or telecommunications line.

frame relay

A high-speed packet-switching service offered by telcos and long-distance carriers and used primarily for corporate wide area network (WAN) links.

Overview

Frame relay technology is a packet-switching service with transmission speeds ranging from 56 kilobits per second (Kbps) for DS-0 or ISDN, to 1.544 Mbps for DS-1 or T1, and even sometimes to 45 Mbps for DS-3 or T3. Frame relay is independent of network-level protocols and can thus carry network traffic of all types, including Transmission Control Protocol/Internet Protocol (TCP/IP), Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX), AppleTalk, DECnet, and Systems Network Architecture (SNA).

Frame relay offers both guaranteed bandwidth necessary for most client/server communications and also accommodates "bursty" traffic when demand for bandwidth suddenly increases, as when a file transfer occurs. Because of these features, frame relay has been a popular solution in the enterprise to connect remote branch offices over frame relay WAN links to corporate headquarters.

Frame relay services are available from all major carriers and Regional Bell Operating Companies (RBOCs).

History

The standardization process for frame relay began in the late 1980s, but it was not until the start of the 1990s that commercial frame relay services began to be available from major telecommunications carriers. The impetus for frame relay originally came from Integrated Services Digital Network (ISDN) technologies—in fact the data-link layer of frame relay is Link Access Protocol-D (LAPD) and is borrowed directly from ISDN.

Frame relay is similar in operation to X.25, an earlier CCITT packet-switching technology from which it also evolved. Frame relay, however, is a more streamlined protocol that has lower latency and thus better performance than X.25. This improvement is possible because frame relay is transmitted over digital lines as opposed to analog lines for X.25. Since analog lines are “noisy,” X.25 required additional protocol overhead for handling error correction and retransmission of bad packets. By contrast, the digital lines used by frame relay have very little noise, with the result that the error correction and retransmission functions can be moved from the protocol itself to the end stations. This results in much lower latency and hence faster transmission in frame relay than in X.25. Frame relay also does not support the hop-by-hop flow control functions that X.25 supports, which further streamlines the operation of frame relay.

Frame relay services were first offered in 1992 as a faster alternative to X.25 by AT&T, Sprint, and other long-distance carriers. These carriers established POPs (points of presence) major metropolitan locations to provide a means of connecting customers to frame relay services. Frame relay is now a popular solution for building corporate WANs and is available from Incumbent Local Exchange Carrier (ILECs), Competitive Local Exchange Carrier (CLECs), RBOCs, and European Post, Telephone, and Telegraph (PTT) companies all around the world.

Uses

Frame relay is primarily used for connecting corporate local area networks (LANs) into a WAN. In the early 1990s, WAN links were mainly used for batch transfers

between remote offices and mainframes at corporate headquarters. For this scenario, frame relay was ideal since companies only accrued charges when the service was actually being used—in between batch transfers, no charges were incurred. With the rise of client/server computing, frame relay remained the best alternative to more expensive leased lines for WAN links between remote offices, and frame relay is today the most popular and widely deployed carrier service for such WAN links.

Most corporate frame relay WAN links use T1 circuits and carry data at rates between 64 kilobytes per second (Kbps) and 1.544 Mbps, with 256 and 512 Kbps being typical values. Until a few years ago, these values sufficed for most remote branch connectivity solutions, but with the explosion of the Internet the bandwidth requirements for corporate WAN links have risen. There are a number of solutions for providing frame relay links beyond T1 speeds (1.5434 Mbps), including

- **Bonding:** This method allows a maximum of two T1 circuits to be joined together to provide 3 Mbps throughput.
- **Multiplexing:** This method allows many DS-1 (another name for T1) circuits to be joined together to provide NxDS-1 frame relay at speeds from 3 Mbps upward. In this scenario the first DS-1 circuit functions as the management circuit for the entire multiplexed group of circuits—if this circuit goes down, connections are broken. Routers with V.35 interfaces support multiplexing of up to about 6 DS-1 circuits, beyond that routers having a faster High-Speed Serial Interface (HSSI) are required.
- **Channelized DS-3:** Multiplexing a large number of DS-1 circuits can be costly. Instead, a single DS-3 (that is T-3) circuit can be “channelized” to provide fractional DS-3—that is, only a portion of the 45 Mbps that a full DS-3 circuit can provide. Implementing channelized DS-3 for frame relay usually requires specialized equipment such as an M13 (DS-1 to DS-3 multiplexer).

- **Full DS-3:** This is the heavy hitter of frame relay services and involves deploying a T-3 circuit to connect a “big iron” frame relay router at your Customer Premises Equipment (CPE) to the carrier. Only a few carriers provide full DS-3 frame relay services.

Architecture

Frame relay is a connection-oriented service similar to X.25 and Asynchronous Transfer Mode (ATM). Frame relay differs from X.25 mainly in eliminating the complex layer-3 error detection and retransmission mechanisms of X.25. Frame relay is thus a simple layer-2 or data-link layer technology that is simple, fast, and independent of higher protocol layers. Although X.25 defines explicit processes for error correction, acknowledgements, packet sequencing, and so forth, in frame relay these functions are handled by the frame relay devices themselves, giving frame relay connections a much lower latency than X.25 connections. In fact, the protocol overhead for frame relay is only about 2 percent compared to almost 50 percent for X.25.

Frame relay is sometimes classified as an “unreliable” service because it performs no error checking or retransmission—if frames become corrupted or delayed by network congestion, they are silently dropped. To make frame relay a reliable service is the responsibility of the frame relay equipment at the ends of the connection, which performs error checking and retransmission and provides flow control.

A carrier’s frame relay network is typically depicted as a “cloud” of connections. This cloud is better known as a Frame Relay Bearer Service (FRBS) and physically consists of the collection of ATM/ Synchronous Optical Network (SONET) trunk lines and switches owned by the carrier. As in other packet-switching networks, frame relay operates by packaging network data into “packets” and tagging each packet with address information (discussed below). In frame relay these packets are called frames and are variable length in nature with payload up to 4 kilobytes (KB), making them especially suitable for carrying network traffic such as Internet Protocol (IP) traffic since entire IP packets can be packaged within individual frames without the need to fragment the packets.

Once frames are transmitted onto the FRBS, they are relayed through the switching nodes that make up the FRBS. Instead of relaying each frame individually, frame relay uses virtual circuits (VCs) that act as logical paths through the carrier cloud. These virtual circuits can be either switched virtual circuits (SVCs) that are set up and torn down on a call-by-call basis or permanent virtual circuits (PVCs) that are established in advance. PVCs are generally preferred because they provide a more reliable grade of service for the customer. PVCs provide dedicated point-to-point connections between local and remote customer premises through the cloud. The particular virtual circuit to which a frame belongs is determined by the frame’s address information or Data Link Connection Identifier (DLCI), a 10-bit binary value that identifies the frame to the carrier switches within the FRBS. The DLCI is a logical value that uniquely identifies the two end points of the virtual circuit.

Frame relay lets you establish multiple PVCs (and hence multiple logical WAN links) over one physical frame relay connection using statistical time-division multiplexing (STDM). You manage frame relay PVCs using the Local Management Interface (LMI) protocol, which provides features for verifying link integrity and managing the status of PVCs. Frame relay PVCs provide customers with services similar to those of dedicated leased lines such as T1 lines, but since frame relay PVCs are software-implemented instead of hardware-implemented on carrier switches, frame relay is faster and easier to provision and costs less than leased lines.

There are two ways of connecting to a frame relay network:

- **UNI:** Stands for User-Network Interface, this is a signaling method for connecting data terminal equipment (DTE) to an FRBS.
- **NNI:** Stands for Network-Network Interface, this is a signaling method for connecting trunk lines together from two different FRBSs (clouds belonging to different carriers).

Frame relay provides customers with a predefined level of service called the Committed Information Rate (CIR) that is agreed upon by the carrier and customer in

advance. CIR is a negotiated level of service you purchase from the carrier that specifies the guaranteed minimum throughput for your frame relay connection. CIR acts as a kind of bandwidth throttling mechanism that facilitates the use of shared frame relay circuits by different users and prevents carriers from oversubscribing their services. Frame relay also allows temporary bursts of traffic to greatly exceed the CIR, thus providing bandwidth-on-demand for customer applications that require it. Bursts of traffic above the CIR are generally short (less than two seconds in duration) and are possible only during off-peak utilization times. When access to the service provider's frame relay network is heavy, your maximum bandwidth will generally be your CIR. Traffic above a higher service level called the Committed Burst Rate (CBR) is flagged as expendable and is dropped if the network is too busy to carry it.

Frame relay is capable of encapsulating IP traffic for transmission over a FRBS. The encapsulation of IP packets by frame relay frames is performed using the High-level Data Link Control (HDLC) protocol described in RFC 2427.

Implementation

The physical layer or Layer 1 for frame relay is the same as ISDN and T-carrier services, and as a result end stations are typically connected to a carrier's frame relay services using T1 or T3 circuits. Frame relay connections can thus be established using any customer premises equipment (CPE) that supports T-carrier services, including many bridges, routers, and switches. Alternatively, a dedicated frame relay device called a FRAD (Frame Relay Access Device) can be installed at the customer premises to connect the customer's network to an Edge Switch (ES) on the carrier side. Most frame relay-capable routers can be configured to operate either as customer-side or carrier-side equipment, but carriers themselves use special "big iron" routers and switches for establishing their cloud of frame relay circuits.

Frame relay. A typical frame relay WAN link.

To set up WAN links between several of your company's locations using frame relay, you typically lease the following services and equipment for each location:

- A FRAD or some other device, such as a Cisco router, that is capable of supporting frame relay connections. The FRAD at your customer premises is the data terminal equipment (DTE) side of the connection, and the frame relay/ATM switch at the telco end represents the data circuit-terminating equipment (DCE) end of the connection. Your CPE FRAD is usually connected to your network's back-

bone switch or router using an RS232, V.35, or X.21 serial interface.

- A T1 circuit to connect the FRAD to the carrier network. Even though you may only want to provision a 256 Kbps frame relay link, most carriers require you to purchase a full 1.544 Mbps T1 circuit to do this instead of a fractional T1 circuit.
- The required number of virtual circuits to support the number of WAN links you need and the speeds they require. Although frame relay intrinsically supports SVCs, few carriers offer this option because it is more expensive and complicated to implement and more complex for billing purposes than PVCs. A single frame relay physical port can have multiple PVCs configured on it.
- The CIR required for each of your WAN links to guarantee the necessary bandwidth for your applications to function optimally over these links. Choose a CIR that is just sufficient to handle your needs to minimize costs, because the higher the CIR, the greater the cost.

If you have more than two remote networks to connect using frame relay WAN links, you have to decide on the topology you want the carrier to provide for you. Frame relay implementations usually follow one of two networking topologies:

- **Fully meshed topology:** In this implementation, each remote location with a FRAD is connected to every other location with a FRAD using PVCs to form a fully meshed multipoint WAN. When an update is transmitted to one device, it is seen by every other device as well. The advantages of this configuration are the redundancy provided within a multipoint mesh network and that the entire frame relay network can be treated as a single data-link connection. The disadvantage is that the number of PVCs needed grows exponentially with the number of locations, and frame relay carriers usually charge per PVC. So this is not really a good solution for more than three remote locations.
- **Partially meshed topology:** This implementation uses a hub-and-spoke topology in which FRADs at

branch offices (spokes) are connected by point-to-point connections to the FRAD at the head office (hub). There is no redundancy in this scenario, so typically redundancy is added by providing backup dial-up ISDN links between branch offices and headquarters in case a frame relay link goes down. This scenario must be carefully implemented to avoid split-horizon problems (routing loops).

Advantages and Disadvantages

Frame relay has several advantages over X.25 that has led to the almost complete demise of the earlier technology and its being superseded in the 1990s by frame relay. These advantages include low protocol overhead, low latency, and easy integration with ATM. Originally, when frame relay was developed in 1992, some observers thought that it would soon be superseded by Switched Multimegabit Data Services (SMDS), a packet-switched service that operates at faster speeds than frame relay and does not use PVCs. But apart from MCI Worldcom, few other carriers decided to provision SMDS and instead offer ATM as their top-speed WAN service. If we think of X.25 as the first generation of wide-area packet-switching carrier services, then frame relay is second generation (2G) and ATM is third generation (3G). Although many industry observers expected frame relay itself to be superseded by ATM for WAN connections, this has not occurred, mainly due to the complexity of implementing ATM. Frame relay has also superseded Digital Data Services (DDS), another early WAN service provided by carriers in the early 1990s.

Frame relay also has advantages over dedicated leased line services such as ISDN and T-carrier services. In general, frame relay is less than half the cost of leased lines of equivalent throughput, and, unlike some leased line services, frame relay's cost is independent of distance. Frame relay PVCs are also easier to provision and can be configured more quickly than ISDN or T1 lines. Because frame relay provides bandwidth-on-demand and is charged the same way as regular long-distance services (that is, by usage), using it for WAN links can result in considerable cost savings over leased lines, which rack up charges even when not in use. Finally, frame relay only requires a single router or FRAD at each remote site, even in a fully redundant mesh

topology, but deploying multiple leased lines at a site requires additional CPE for each line, incurring further cost and adding management headaches.

The many advantages of frame relay ensure its continued survival in the jungle of today's WAN marketplace. Frame relay is simple in concept and in implementation, has established itself as a reliable solution, has an easy-to-understand pricing structure, is cheaper than other comparable services, supports up to 1024 virtual circuits per WAN to meet the needs of even the largest enterprise, is offered by carriers around the world, and has the intrinsic security of point-to-point connections. The only real challenge to its dominance in the WAN is from upstart Digital Subscriber Line (DSL) coupled with IP VPN (virtual private network) technology, which is discussed later in this article.

Marketplace

The three largest providers of nationwide frame relay services in the United States are the Big Three long distance carriers—AT&T, Sprint Corporation, and MCI Worldcom. Sprint, in fact, was the first carrier to offer CIR for its frame relay subscribers, something that is now universally available. AT&T and Sprint between them have more than 1500 POPs nationwide, which provide good coverage for large enterprises using frame relay for their WAN service. Various RBOCs such as BellSouth Corporation, Bell Atlantic/GTE, and Qwest/US West also provide frame relay services, but with fewer POPs and covering specific geographical regions. Other providers of frame relay services include CLECs such as Intermedia Communications and WinStar Communications.

Although most carriers offer DS-1 frame relay services with CIR up to 1.544 Mbps, enterprises that need higher speeds for frame relay WAN links are more limited in their choice of providers. BellSouth now offers an NxDS-1 frame relay service called Subrate T3 that lets customers choose various frame relay rates between 2xT1 bonding (3 Mbps) and full T3 (45 Mbps). Instead of using a traditional conditioned copper T1 circuit at the customer premises, customers implementing this new service use a fiber T3 circuit, which allows them to upgrade to full T3 if eventually required. A few other

carriers offer similar NxDS-1 frame relay services and fewer still offer full DS-3 frame relay. For the few customers requiring speeds higher than DS-3 (45 Mbps) for WAN connectivity, ATM can be used instead of frame relay. If a company has a mix of frame relay and ATM in its WAN, it must choose one of two methods for making these technologies interoperate: FRF.5, which tunnels frame relay over ATM, or FRF.8, which translates frame relay frames into ATM cells. An alternative to ATM for high-speed WAN connectivity that is just starting to emerge is Optical Ethernet, offered by carriers such as Yipes, which can provide Gigabit Ethernet (GbE) to the door WAN services. This is an attractive development that may shake the market up considerably in the next few years, but frame relay and ATM still reign supreme in the international arena and for long-haul WAN links.

The prohibitive costs of building a fully meshed frame relay topology for companies with multiple locations has recently been surmounted by a new service offered from AT&T called IP-enabled Frame Relay (IPFR) and a similar service from MCI WorldCom called Business Class IP. In these new scenarios, each branch office is connected to the carrier's frame relay cloud using a single PVC as in a normal hub-and-spoke implementation. However, each frame is tagged using Cisco Systems' proprietary Multi-Protocol Label Switching (MPLS) technology, which allows traffic to be routed across the cloud using destination IP addresses instead of virtual circuit identifiers. The result is the equivalent of a VPN in an IP network. In a hub-and-spoke network, each frame is first sent to the head office FRAD and then forwarded to the appropriate branch office LAN; in the MPLS scenario, however, frames can be routed directly to their destination LAN. All the switching is done by the carrier's core network (usually ATM), which relieves the FRADs of the additional processing they would otherwise need to do in a normal full-mesh network with multiple PVCs at each site.

Although frame relay supports the capability of billing customers according to usage, most providers bill at flat rates based on the number of frame relay ports, number of virtual circuits, and CIR.

Prospects

Frame relay, despite rumors to the contrary, is still on the rise. Industry analysts predict the frame relay market will be \$6 billion in 2002, and this is expected to double over the next five years.

Although costs for leased lines in North America have fallen somewhat in recent years, frame relay still provides equivalent services for WAN connectivity for about half the cost as leased lines. In Europe, prices for leased lines have fallen much more sharply than in the United States, and frame relay is considered to be on a par with leased lines there. In the Asia/Pacific region, however, leased lines are still expensive and most companies use frame relay for linking their regional offices to U.S. offices.

The biggest challenge to frame relay is DSL services now being offered by telcos. DSL can provide frame relay speeds for rock-bottom costs of \$50 a month or less. However, DSL is not seen yet to have the same reliability as frame relay, and although widely deployed for residential Internet access, it is not seen by most enterprises as ready for prime-time WAN links that carry mission-critical business traffic. Most DSL deployments involve the cooperation of several parties including CLECs, ILECs, and Internet service providers (ISPs). As a result, when DSL goes wrong, it can take weeks or even months to troubleshoot, with everyone pointing fingers at one another. With frame relay, however, the customer only needs to deal with one provider, or two if User-to-Network Implementation (UNI) services are provided since Network-to-Network Implementation (NNI) services are provisioned directly from the carrier. This makes both provisioning and troubleshooting of frame relay links a snap compared to DSL. Another advantage of frame relay in the WAN is security—frame relay links are point-to-point connections that cannot be hijacked or pirated. By contrast, for companies to use DSL in the WAN, they need to deploy a VPN over the connection to make it secure. Because of all these issues, frame relay is expected to remain a strong player in the corporate WAN marketplace for the next 5 to 10 years until an alternative technology such as DSL makes a compelling case for enterprises to migrate.

Being a packet-switching service, frame relay is inherently poor at carrying delay-sensitive traffic such as voice and video (frame relay was originally designed for carrying data only). Nevertheless, recent advances have led to the provisioning of Voice over Frame Relay (VoFR) services by some carriers, and it remains to be seen how these services will evolve in the marketplace.

Notes

The following table shows some possible strategies for troubleshooting frame relay links in different kinds of situations.

Troubleshooting Frame Relay Links

<i>Problem</i>	<i>Suggestions</i>
Frame relay link is down (connections fail)	Check cabling and connections, make sure you are using a data terminal equipment (DTE) cable, try connecting the cable to a different port, or try a different cable. Make sure you are using Internet Engineering Task Force (IETF) encapsulating if mixing frame relay devices from different vendors.
Cannot ping remote router	Check the status of PVC; contact carrier if this is down. Check the router's access list, disable access list, and retry. Make sure you are using IETF encapsulating if mixing frame relay devices from different vendors. Check the configuration of the frame relay address map.
Cannot ping device on remote network	Try pinging local router's frame relay address; check that a default gateway is specified. Check for split horizon conditions in a hub-and-spoke frame relay implementation.

Frame Relay Access Device (FRAD)

A telecommunications device that enables a customer site to be connected to a telco's frame relay services.

Overview

F A Frame Relay Access Device (FRAD) is a device that accepts data packets from the customer's network and encapsulates them into a format acceptable for transmission over a T-carrier circuit to a telco's frame relay network. Some FRADs can also statistically multiplex several frame relay virtual circuits (logical data streams) into a single physical communication circuit to support fully meshed frame relay wide area networks (WANs). Statistical multiplexing enables FRADs to provide customers with greater flexibility in bandwidth use, in contrast to time-division multiplexing (TDM) techniques, which ensure a full level of service for each data stream, even when they carry no data. For example, if two data streams are multiplexed using TDM, frames from the two streams will alternate to form the single serial data link. If one of these streams has no data, empty frames will still be sent, resulting in a poor utilization of bandwidth. In statistical multiplexing, the multiplexed data stream contains only frames from data streams that are carrying data, and the higher the data transmission rate of a stream, the greater the number of frames that are multiplexed into the serial data link.

Implementation

A FRAD is typically connected to a bridge, router, or switch attached to your network backbone (some FRADs also have built-in switching and routing capabilities, too). The FRAD accepts network packets, buffers and frames them, and then transmits them over a T1 or T3 circuit to an Asynchronous Transfer Mode (ATM)/frame relay switch at the telco central office (CO).

The FRAD at the customer premises end is the data terminal equipment (DTE) end of the WAN link and typically connects to a router or switch on the customer's backbone network using a serial interface such as RS-232, X.21, or V.35. The switch at the CO end represents the data circuit-terminating equipment (DCE) end of the link and often interfaces directly to the telco's ATM trunk line network.

Some bridges and routers, such as many of those from Cisco Systems, have built-in FRAD technology and need to be connected only to a CSU/DSU (Channel Service Unit/Data Service Unit) through a V.35 or other serial transmission cable to provide customers with an all-in-one frame relay access solution for wide area networking. Use a bridge if you want an easy way to connect a branch office using frame relay. Use a router if you want to control traffic flow or reroute failed connections.

Marketplace

FRADs come in all shapes and sizes from networking vendors and often are described as switches, routers, or access devices instead of FRADs. The reason is that these devices tend to be able to perform several functions, and different vendors classify these functions differently.

Two popular FRADs in enterprise networks are the Net-performer SDM-8200 from ACT Networks and Cisco's 2600 series routers. 3Com Corporation, Openroute Networks, Motorola ING, Fastcomm Communications, IBM, Alcatel, and many other vendors also sell FRADs.

Sometimes called a Frame Relay Assembler/Disassembler.

frame relay cloud

The totality of frame relay circuits within a telecommunication carrier's frame relay network.

Overview

A carrier's frame relay network is commonly known as a frame relay cloud, but the more technically correct term is Frame Relay Bearer Service (FRBS). Typically, a frame relay cloud is a collection of packet-switching devices owned by the carrier and used as a shared public network for backboning wide area network (WAN) traffic for private customers. Frame relay clouds can also consist of frame relay circuits owned by private networking consortiums. The frame relay network is described as a "cloud" because of the large number of interconnections between the various edge switches,

usually forming a fully connected mesh topology. In frame relay services, each frame of information contains the routing information needed to enable the frame to be routed to its destination through the cloud.

frame tagging

A method developed by Cisco Systems for building multiswitch virtual local area networks (VLANs).

Overview

A VLAN consists of a collection of ports on an Ethernet switch that acts as if it were a separate LAN from the remaining ports. In other words, you can segment a network into several VLANs using only one Ethernet switch to create smaller broadcast domains.

Frame tagging is a mechanism developed by Cisco to identify which VLAN a packet belongs to. Frame tagging encapsulates a packet into a frame containing the VLAN ID of the packet. When a tagged packet leaves the switch and arrives at another switch, the second switch can determine which VLAN the packet belongs to and switch it accordingly. The result is that frame tagging can be used to build VLANs that span more than one switch, and the process is scalable to the enterprise level.

Frame tagging is implemented in Cisco Catalyst switches and is widely used for building enterprise VLANs.

frame type

Specifies the data format for frames when using the NWLink IPX/SPX-Compatible Transport on machines running Microsoft Windows 2000, Windows XP, and Windows .NET Server.

Overview

Two machines on a network using NWLink must be using the same frame type to communicate. NWLink on Windows 2000, Windows XP, and Windows .NET Server can listen to Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) traffic on the

network and automatically configure itself to use the network frame type, which is usually

- 802.3 for NetWare 2.2 through 3.11
- 802.2 for NetWare 3.12 and later

The following table shows the frame types supported by NWLink.

Supported NWLink Frame Types

Topology	Frame Types Supported				
	Ethernet II	802.2	802.3	SNAP	802.5
Ethernet	x	x	x	x	
Token Ring				x	x
FDDI		x		x	

Notes

NWLink on Windows 2000 Server and Windows .NET Server lets you configure multiple frame types if needed, but if multiple frame types are detected where one of them is 802.2, then the 802.2 frame type will be selected by default. NWLink on Windows 2000 Professional and Windows XP Professional can be configured for multiple frame types only by editing the registry.

Free Space Optics (FSO)

The transmission of data through free space using lasers.

Overview

Free Space Optics (FSO) was conceived 20 years ago when fiber-optic technology was still in its infancy. The promise of FSO has only begun to be commercially realized, however, in the last couple of years.

FSO sends data using modulated laser beams through the air without wires or cables. It can be used to connect networks together and to link networks to high-speed wide area network (WAN) services provided by carriers. It can work with any networking architecture but is most commonly used to transport Internet Protocol (IP) packets. It is fundamentally similar to microwave communications but operates in the terahertz frequency range of infrared and visible light.

Implementation

FSO is a line-of-site (LOS) technology that supports point-to-point, multipoint, and fully meshed networking topologies. Point-to-point connections enable data to be carried up to gigabit speeds over distances of several miles. Multipoint connections tend to be lower in speed, but fully meshed topologies can provide a measure of fault tolerance and resiliency in case of link failure.

Advantages and Disadvantages

The main advantage of FSO over traditional fiber networking is that it is cheaper and easier to deploy. The cost of laying new fiber from a telco central office (CO) to a customer's building can run in the hundreds of thousands of dollars, and it takes weeks or months to be provisioned. By contrast, a point-to-point FSO link can be established between two buildings in a matter of days and for a fraction of the cost.

Since FSO operates in an unregulated portion of the frequency band, no additional licensing costs are required to implement the technology. This cost savings can be passed down to customers, making FSO an attractive alternative to fiber. A factor in favor of FSO deployment is that some analysts estimate that 90 percent of buildings in the United States do not yet have fiber deployed to them by carriers.

On the negative side, FSO has some issues associated with its deployment and usage. Since it is a line of sight technology, interference from buildings, airplanes, birds, and weather can interrupt service, reducing FSO's reliability to well under the 99.999 percent rating of conventional fiber-based carrier services. Often the best solution for FSO providers is to establish a backup network to handle these situations, and a typical such network would be a set of point-to-point microwave links (microwaves can be affected by rain but are impervious to the fog and pollution that can interfere with FSO transmissions).

Another issue is that the buildings on which FSO transceivers are mounted tend to sway in the wind and even change size and shape with the seasons, making it com-

plex to align FSO transmissions accurately. Obtaining rooftop right-of-way to deploy FSO equipment often proves costly, but some vendors have reacted by producing transceivers that can be mounted inside offices and transmit their laser beams through windows.

There is also the issue of public perception of safety hazards associated with FSO, namely of having invisible laser beams running all over the place. Although FSO transceivers typically generate less intensity than a laser pointer, safety is still considered an issue of public import and the U.S. Food and Drug Administration (FDA) will probably set specific guidelines in this area.

Marketplace

The number of vendors and service providers offering FSO has been exploding recently. Some of the vendors offering FSO equipment include AirFiber, LightPointe, Terabeam Corporation, and many others.

Service providers Tellaire and Broadband Highway also offer metropolitan area networking (MAN) services in a number of major cities across the United States.

Frequency Division Multiple Access (FDMA)

The signal multiplexing technology used in the AMPS (Advanced Mobile Phone Service) cellular phone system.

Overview

Frequency Division Multiple Access (FDMA) is one of three methods used for allocating channels to users over the shared wireless communications medium in cellular phone communication; the others are Time Division Multiple Access (TDMA) and Code Division Multiple Access (CDMA). FDMA is the oldest of these methods and is used in the analog AMPS cellular phone system still widely deployed throughout the United States and some other parts of the world. FDMA is also used by traditional AM and FM radio bands to allow broadcast by individual stations and by the CT2 communications system used for cordless telephone systems.

Implementation

FDMA is based on frequency-division multiplexing (FDM) and is implemented at the media access control (MAC) layer of the data-link layer in the Open Systems Interconnection (OSI) reference model. One way to understand FDMA is to imagine different people in the same room communicating in voices with different pitches, some high and some low; they'd all be able to talk simultaneously and (more or less) understand one another.

Frequency Division Multiple Access (FDMA). How FDMA works.

In the AMPS cellular system that is based on FDMA, each user is assigned a specific channel (frequency band) in the allotted electromagnetic spectrum, and during a call that user is the only one who has the right to access the specific band. These frequency bands are allocated from the electromagnetic spectrum as follows:

- **Transmission by mobile station:** 824 megahertz (MHz) to 849 MHz
- **Transmission by base station:** 869 MHz to 894 MHz

Two different frequency bands are used to allow full-duplex communication between base and mobile stations. Both of these bands are then divided into discrete channels that are 30 kilohertz (kHz) wide in bandwidth.

Advantages and Disadvantages

One disadvantage of FDMA is that only one subscriber can be assigned at a time to a particular channel within a cell. Once the channel is allocated, it remains the pos-

sion of the subscriber until the call is terminated or the subscriber roams outside the cell.

frequency-division multiplexing (FDM)

A signal transmission technology in which multiple signals can simultaneously be transmitted over the same line or channel.

Overview

Frequency-division multiplexing (FDM) can be used in both wired and wireless networking for transmitting large amounts of data at high speeds. FDM is the simplest and oldest form of multiplexing in wireless networking technology.

FDM involves simultaneously transmitting multiple signals on different frequencies. These different frequencies, called channels, share nonoverlapping portions of the total frequency band being used. Signals from different data sources are fed into a multiplexer that modulates each signal and transmits them at different frequencies. These signals are then transmitted over the wire or through wireless communication and are separated at the destination into individual data signals using a demultiplexer.

Uses

FDM is used in a number of popular technologies including cable television (primarily within Hybrid Fiber Coaxial [HFC] cable systems), microwave and satellite networking, and in the older Advanced Mobile Phone Service (AMPS) cellular phone system.

frequency hopping

A spread-spectrum transmission technology for wireless networking.

Frequency hopping. How frequency hopping works.

Overview

Spread-spectrum wireless technologies trade throughput for increased reliability and were originally developed by the U.S. military to provide communication that could not easily be jammed. Frequency hopping transmitters take the incoming data stream and segment it into multibit packets. These packets are then transmitted sequentially in a pseudo-random manner over the various frequency channels within the spread-spectrum band being used. In other words, the frequency of the carrier signal keeps hopping around. Synchronization between the master transmitter and slave devices is achieved by modulating the center or carrier frequency of the communication band according to a preset algorithm. Both the mobile and the base station know the modulation algorithm, which enables them to keep in communication with each other. For increased security, the modulation algorithm can be dynamically modified.

Frequency hopping is employed in cellular communications systems and some wireless networking systems. It is also used in Bluetooth PAN (personal area network) technologies.

Frequency Hopping Spread Spectrum (FHSS)

Any type of wireless communications system based on frequency hopping.

Overview

Frequency Hopping Spread Spectrum (FHSS) is the earliest secure transmission mechanism used for the physical layer of wireless communications. FHSS was conceived as a technology by actress Hedy Lamarr and composer George Antheil during World War II and became popular as a secure communications system that was resistant to eavesdropping.

Implementation

FHSS employs a narrowband carrier and divides communications up into a number of discrete channels. Information is transmitted in a series of short bursts that hop from one frequency to another. To a non-FHSS receiver, the transmission seems to be random bursts of noise. To make FHSS work, both the transmitter and receiver are programmed with the same hopping sequence and are synchronized with each other so that the receiver always knows what frequency the transmitter is going to hop to next. If interference is encountered on a channel, the transmission for that channel is discarded and retransmitted on the next hop, making FHSS an efficient means of communication in noisy environments.

Uses

FHSS is one of the three PHY layer technologies defined by the 802.11 wireless networking standard, the others being Direct Sequence Spread Spectrum (DSSS) and infrared. Although early 802.11 radio equipment employed FHSS, the newer 802.11b standard does not support FHSS and uses DSSS instead.

Another technology that uses FHSS is Bluetooth, a short-range wireless networking technology for building personal area networks (PANs).

frequently asked questions (FAQ)

A list of commonly asked questions and their answers.

Overview

Frequently asked questions (FAQ) are usually developed for beginners in a given subject to reduce the amount of customer technical support required. They are often available for computer products and services on company and organization Web sites on the Internet, as well as for many different Usenet newsgroups. Some Microsoft software documentation also includes FAQs to provide quick answers to commonly asked questions about the software. To ease your customer support requirements, create simple and highly usable FAQ for your clients.

FSM

Stands for File and Print Services for Macintosh, a Microsoft Windows 2000 service that provides Macintosh users with access to files stored on NTFS volumes on Windows 2000 file servers.

See: *File and Print Services for Macintosh (FSM)*

FSMO

Stands for flexible single-master operation, a unique set of single-master roles for domain controllers in Windows 2000 and Windows .NET Server networks.

See: *flexible single-master operation (FSMO)*

FSO

Stands for Free Space Optics, the transmission of data through free space using lasers.

See: *Free Space Optics (FSO)*

FTAM

Stands for File-Transfer Access and Management, the Open Systems Interconnection (OSI) reference model counterpart of the Internet standard File Transfer Protocol (FTP).

See: *File-Transfer Access and Management (FTAM)*

FTP

Stands for File Transfer Protocol, an application-level protocol that can be used for transferring files between hosts on a Transmission Control Protocol/Internet Protocol (TCP/IP) network.

See: *File Transfer Protocol (FTP)*

FTP service

A Microsoft Windows NT service on servers running Microsoft Internet Information Server, or a Windows 2000, Windows XP, or Windows .NET Server service on servers running Internet Information Services (IIS).

Overview

The FTP service supports the Internet standard File Transfer Protocol (FTP) and allows users to upload and download files between FTP clients and FTP servers. IIS FTP servers support only anonymous authentication or Basic Authentication. When an FTP client attempts to connect to an FTP server configured to use Basic Authentication, the user's name and password are transmitted as clear text over the network, which is insecure. The best way to secure FTP services is to enable anonymous authentication on all FTP servers, which requires users to log on with the username "anonymous." (They can enter anything for the password, but the FTP server's welcome message usually requests politely that they use their e-mail address as their password for logging purposes.) You should configure the FTP service on IIS to allow only anonymous logons to prevent users from passing their credentials over the network. Then simply avoid storing critical information on your FTP servers and use them for access to public information only.

You will probably also want to configure your FTP servers to allow only downloads and prohibit all uploads. If your corporate users must upload files remotely using FTP, you can create an FTP drop box for them. An FTP drop box is a folder on an NTFS volume, configured as a virtual directory that has write permission on it but not read permission. In other words, users can upload files to the directory but cannot read what has already been uploaded.

F

FTTC

Stands for fiber to the curb, the laying of fiber-optic cabling by telcos to the customer premises.

See: fiber to the curb (FTTC)

full backup

Commonly called a normal backup in Microsoft terminology, a backup type in which an entire volume or system is backed up.

See: normal backup

full-duplex

A mode of communication in which data is simultaneously transmitted and received between stations.

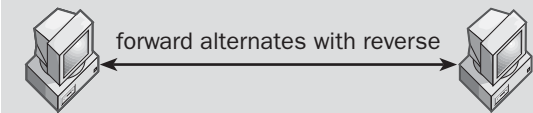

Overview

Full-duplex communication is twice as fast as half-duplex communication and typically uses two separate pairs of wires (or two channels for wireless networking) for supporting simultaneous transmission and reception by a host. An alternative arrangement is to use some multiplexing technique, such as time-division multiplexing (TDM), to interleave transmission and reception on a single channel. This does not produce true full-duplex communication, but to an ordinary user it might appear to do so if the interleaving process is fast enough.

Simplex

Half-duplex

Full-duplex

Full-duplex. Full duplex communications compared to simplex and half-duplex.

Examples of full-duplex communication include cellular telephone technologies and full-duplex Ethernet. Examples of half-duplex communication are walkie-talkies, CB radios, and standard Ethernet networks. Examples of simplex communication technology include satellite broadcasting and cable TV broadcasting.

full-duplex Ethernet

A form of Ethernet that supports full-duplex communication between stations on the network.

Overview

Full-duplex Ethernet lets stations send and receive data simultaneously, thus giving it twice the maximum throughput of traditional forms of Ethernet. Full-duplex Ethernet uses two wires for sending and receiving data simultaneously.

Full-duplex Ethernet. Using full-duplex Ethernet to connect local area networks (LANs) using long-haul fiber.

Full-duplex Ethernet does not use the traditional Carrier Sense Multiple Access with Collision Detection (CSMA/CD) media access control method of traditional half-duplex Ethernet since collisions cannot occur on a full-duplex, point-to-point link between two stations. Instead, full-duplex Ethernet uses dedicated point-to-point connections between stations where collisions cannot occur. To implement these point-to-point connections, you must use Ethernet switches instead of traditional hubs or repeaters since hubs are shared media devices and cannot provide dedicated connections.

Using switches means that full-duplex Ethernet avoids the collisions that can degrade the performance of standard half-duplex Ethernet. In theory, a full-duplex connection on a 100 megabits per second (Mbps) Fast Ethernet network has a maximum speed of 200 Mbps. In reality, however, full-duplex Ethernet tends to achieve only a 20 to 60 percent higher throughput than regular half-duplex Ethernet.

The table below shows which varieties of Ethernet support both half-duplex and full-duplex signaling and which are restricted to half-duplexing only.

Ethernet Media Options Supporting Full-Duplex Signaling

Media specification	Full-Duplex Supported
10Base2	
10Base5	
10BaseT	X
10BaseFL	X
10BaseFB	
10BaseFP	
100BaseTX	X
100BaseT2	X
100BaseT4	
100BaseFX	X
1000BaseCX	X
1000BaseLX	X
1000BaseSX	X
1000BaseTX	X

Uses

Because the distance limitations between two stations in full-duplex Ethernet depend only on the strength of the transceivers with respect to the medium used,

station-to-station distances for full-duplex Ethernet connections can be much greater than for traditional Ethernet networks. For 100-Mbps full-duplex links, this is generally around 1.25 miles (2 kilometers) over fiber-optic cabling but using vendor-specific nonstandard repeaters, this can be extended to 62.5 miles (100 kilometers) or more.

You can also use 10-Mbps full-duplex Ethernet to connect two 10BaseT Ethernet networks over duplex single-mode fiber-optic cabling at distances of up to 15 kilometers. To do this, use a pair of half-to-full duplex converters at either end of the fiber-optic line. These converters should always be used in pairs, and they typically have an attachment unit interface (AUI) port that accepts the fiber-optic transceiver.

fully qualified domain name (FQDN)

In the Domain Name System (DNS), a dotted name that fully identifies a Transmission Control Protocol/Internet Protocol (TCP/IP) host on the Internet.

Overview

A fully qualified domain name (FQDN) of a host consists of its host name together with its domain name and any names of subdomains in which the host resides, all of which are separated by periods. FQDNs are used in Uniform Resource Locators (URLs) for accessing Web pages on the Internet and provide an absolute path through the DNS namespace to the target host on which the Web page resides. They are also sometimes called absolute domain names.

Examples

For the host having the FQDN

```
server7.microsoft.com
```

the host name is `server7` and the domain is `microsoft.com`.

G.703

A digital signaling specification from the International Telecommunication Union (ITU).

Overview

G.703 is an ITU recommendation for interfacing DCE (data communications equipment) with digital high-speed synchronous communication services. The G.703 interface covers signaling speeds from 64 kilobits per second (Kbps) to 2.048 megabits per second (Mbps) over a four-wire physical interface. G.703 also supports special data recover features that make it suitable for high-speed serial communications.

G.703. Using a G.703 converter to interface a router to an E1 circuit.

Although G.703 has been updated to include support for U.S. standard T-carrier service speeds, such as T1 transmission at 1.544 Mbps, it's not widely used in North America and is found mainly in Europe. Private Branch Exchange (PBX) systems often use 64-Kbps leased lines using the G.703 standard, as do E-carrier

services such as E1 communication links. Some U.S. vendors sell converters for connecting synchronous V.35, RS-449, RS-232, or X.21 interfaces to G.703 in order to sell their switching equipment in Europe. G.703 converters are also used to interface digital microwave and satellite communication channels and for translating between 56 and 64 Kbps speeds for different serial interfaces. G.703 optical converters can handle speeds of 45 Mbps (E3) and higher.

gateway

A term used to describe a variety of networking technologies that enable communication between different networking architectures and protocols.

Overview

Gateways generally operate at the higher levels of the Open Systems Interconnection (OSI) reference model for networking. They are commonly used to provide connectivity between two different protocol stacks that might be running on different systems. Examples include the following:

- E-mail gateways—for example, a gateway that receives Simple Mail Transfer Protocol (SMTP) e-mail, translates it into a standard X.400 format, and forwards it to its destination
- Gateway Service for NetWare (GSNW), which enables a machine running Microsoft Windows NT Server, or Windows 2000 Server to be a gateway for Windows clients so that they can access file and print resources on a NetWare server
- Gateways between a Systems Network Architecture (SNA) host and computers on a Transmission

Control Protocol/Internet Protocol (TCP/IP) network, such as the one provided by Microsoft SNA Server

- A packet assembler/disassembler (PAD) that provides connectivity between a local area network (LAN) and an X.25 packet-switching network

A gateway is usually a dedicated device or a set of services running on a dedicated computer. Gateways are essentially devices that direct network traffic in some fashion and translate that information.

Gateway Service for NetWare (GSNW)

A feature of Microsoft Windows 2000 Server that allows Windows clients access to NetWare servers.

Overview

When Gateway Service for NetWare (GSNW) is installed and configured on a machine running Windows 2000 Server, the server can act as a gateway to enable Windows clients to access file, print, and directory resources on Novell NetWare servers. The process is totally transparent to the users on the Windows client machines—to them the resources appear to be located on the Windows 2000 server itself instead of the NetWare server.

GSNW can perform gateway functions for all versions of Microsoft Windows client operating systems, including Windows for Workgroups, Windows 95, Windows 98, Windows Millennium Edition (Me), Windows NT Workstation, Windows 2000 Professional, and Windows XP. GSNW can provide gateway access for Windows clients to bindery-based NetWare 2.x and 3.x servers and to NetWare 4.x servers running either NDS (Novell Directory Services) or in bindery emulation mode. A Windows 2000 server that has GSNW installed also must have the NWLink protocol loaded. This protocol, which is an Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX)-Compatible Transport, makes it possible for the Windows 2000 server to communicate with the NetWare server. If it is not already installed, NWLink will install automatically on the Windows 2000 server when you install GSNW.

Implementation

To prepare the NetWare server for the gateway, you must create a group and a user account as follows:

- Create a group called Ntgateway on the NetWare server and give it the necessary rights for accessing the resources you want to make available on the server.
- Create a user account on the NetWare server and give it the necessary rights for accessing the resources you want to make available on the server. Make this user account a member of the Ntgateway group.

Gateway Service for NetWare (GSNW). How GSNW provides Microsoft Windows clients with access to file and print resources on a Novell NetWare server.

GSNW will use this user account for creating a connection to the NetWare server. The connection will appear on the server running Windows 2000 as a redirected drive that can be shared, as if it were a resource located on the Windows 2000 server. Windows clients can then connect to the shared resource by browsing My Network Places, by mapping a drive using Windows

Explorer, or by using the net use command. From the perspective of Windows clients on the network, the shared resources they access appear to reside on the Windows 2000 server. In actuality, the GSNW service on the server is performing protocol conversion between the Server Message Block (SMB) protocol, which the Windows clients understand, and the NetWare Core Protocol (NCP), which the NetWare file server uses.

After GSNW is installed, the first time you log on to the server for connectivity to a NetWare 4.x server using NDS, you are prompted to specify a default tree and context for connecting to the NetWare server. If the NetWare server is running in bindery-emulation mode or is an earlier 2.x or 3.x server, you must specify a preferred server when you log on. You can also configure these settings using the GSNW utility in Control Panel.

Uses

Because GSNW must process all requests directed through the gateway and perform protocol conversion between SMB and NCP, access is slower than if the clients actually had NetWare client software installed and could directly access the NetWare server. You should use GSNW only for occasional or temporary access to NetWare servers by Windows clients—for example, during a process of migrating NetWare servers to Windows 2000. When Windows clients need frequent access to resources on NetWare servers, as in a heterogeneous networking environment, install Client Services for NetWare (CSNW) instead of GSNW on Windows 2000 client machines to allow them direct access to resources on NetWare servers. On other versions of Windows, you can install Client for NetWare Networks to achieve the same result.

Notes

Both GSNW and CSNW are also available on the Windows NT platform.

gender changer

An adapter with two connectors of the same type and gender.

Overview

A gender changer enables you to change the gender of the connector to which it is joined. For example, you could change the gender of a cable connector from male (with pins) to female (with sockets) or vice versa. This is typically done to allow two male or female cable ends to be joined together to form a longer cable or to allow equipment to be connected to a cable with the wrong gender.

Gender changers come in a variety of types and are specified by the connector type and gender involved. An example would be a V.35 to V.35 male/male gender changer, which can be used to connect two V.35 serial cables (or one cable and a Channel Service Unit/Data Service Unit [CSU/DSU]) that terminate with female connectors.

Gender changer. Examples of V.35 gender changers.

Some gender changers can also act as adapters for different data interfaces. For example, a V.35 to RS-232 male/male gender changer can be used to connect a V.35 connection on a CSU/DSU to a router using an RS-232 serial cable. Be sure that the pinning for such a gender changer is suitable for the type of equipment you want to connect because different pinnings might exist when different serial interfaces are connected.

General Packet Radio Service (GPRS)

A 2.5G upgrade to existing Time Division Multiple Access (TDMA) cellular communications systems.

Overview

General Packet Radio Service (GPRS) was designed as an upgrade for existing second-generation (2G) cellular systems such as Global System for Mobile Communications (GSM) and other TDMA systems such as AT&T Wireless. GPRS is a packet-switching overlay that can support Internet Protocol (IP) data transmission at speeds up to 171 kilobits per second (Kbps), which is more than 10 times faster than currently supported data rates for these systems (data transmission on current GSM systems is typically 9.6 Kbps). In practice, however, the maximum data rates are usually more like 52 Kbps downstream and 13 Kbps upstream. This is because of the overhead of combining channels together, throttling of bandwidth by providers to enable more users to share channels, and the power limitations of handsets at the subscriber end.

GPRS will provide the first global high-speed mobile IP communications system and is intended as an interim solution until broadband third-generation (3G) cellular systems can be fully deployed. Using GPRS, a cellular phone can access Internet services by means of Wireless Application Protocol (WAP). WAP provides a richer format for information exchange than the existing Short Message Service (SMS), which is limited to a maximum of 160 characters per transmission. With its higher data rates, GPRS makes possible the kinds of wireless applications and services that simply have not been feasible on

existing GSM and TDMA systems. Possible uses for GPRS include wireless mobile Web browsing, discussion groups, chat services, mobile commerce, and home automation through wireless remote control.

The GPRS standard 03.60 was developed by the European Telecommunications Standards Institute (ETSI). Trials of GPRS began in 1999, and the first commercial rollouts appeared in 2000. A number of European and Asian countries and regions are piloting GPRS systems and thus have an edge over the United States in the arena of wireless communication systems running at more than 20 Kbps.

Uses

Besides cellular phones, GPRS can be implemented in a wide variety of devices, including PCMCIA modems for laptops, expansion modules for Personal Digital Assistants (PDAs) and handheld computers. Research in Motion (RIM), makers of the popular BlackBerry handheld e-mail devices, is working with Microcell Telecommunications, a GSM provider, to use GPRS as a transport for its wireless messaging system.

Architecture

Most existing 2G cellular systems are circuit-switched services in which a dedicated connection must be established in order for communications to take place. As long as the session lasts, the subscriber owns the channel and is billed for its usage even if no data is being sent. By contrast, packet-switching is a more efficient technology because it allows several users to share a channel. No actual connection needs to be established in order to send data—from the point of view of the subscriber the system is “always on” and ready to transmit. And instead of billing for connection time, subscribers are billed according to the amount of data they transmit and receive instead.

GPRS uses the same underlying TDMA time slot architecture as GSM, but instead of assigning only a single time slot to each user for transmission or reception, it can multiplex up to eight slots (the maximum for a TDMA frame) to give a maximum possible data transmission rate of 171 Kbps. In most implementations, however, three or four slots can be multiplexed for

downstream transmission and only one for upstream, which makes practical transmission speeds much slower (but still better than GSM alone).

When a GPRS user wants to send data, the handset finds the first available time slot and sends the first chunk of data, sending more chunks as further slots become available. In this respect, GPRS operates like an Ethernet network—the more users sharing the system, the less bandwidth available for each user to transmit or receive data. Collisions do not occur, however, since time-division multiplexing (TDM) prevents contention from occurring.

GPRS was designed to transport both IP and X.25 packet data, but all current implementations use IP to provide connectivity with the Internet. To provide this connectivity, a GPRS mobile phone needs an IP address, which can be either statically or dynamically assigned. All existing application-layer Internet protocols can run over GPRS, including Hypertext Transfer Protocol (HTTP), File Transfer Protocol (FTP), Simple Mail Transfer Protocol (SMTP), and so on. Most GPRS systems use WAP as their application layer protocol, however, because it is more efficient for devices with limited memory and small displays.

Implementation

Implementation of GPRS requires that existing TDMA hardware be upgraded, including handsets and base stations. In addition to the base stations and mobile switching centers of existing TDMA networks, GPRS adds two additional components:

- **Serving GPRS Support Node (SGSN):** This transmits and receives IP packets to mobile stations through the existing base stations, and exchanges these packets with the Gateway GPRS Support Node (GGSN) using a special tunneling protocol called GPRS Tunneling Protocol (GTP).
- **Gateway GPRS Support Node (GGSN):** This acts as a gateway between the SGSN and the Internet, forwarding packets between them.

GPRS handsets are similar to GSM handsets, and they require a Subscriber Identity Module (SIM), a form of

smart card containing the subscriber's ID, billing address, private key, and other information. GPRS supports several security schemes including Password Authentication Protocol (PAP), Challenge Handshake Authentication Protocol (CHAP), Secure Sockets Layer (SSL), and IPsec.

It is probable that GPRS upgrades will be easiest for carriers whose networks operate in the 1800-megahertz (MHz) or 1900-MHz frequency bands, because they usually have sufficient unused capacity to implement channel aggregation without having to upgrade their bearer equipment. Upgrading to GPRS is more expensive for carriers operating in the 800-MHz or 900-MHz bands because of the near-full capacity of those bands.

Another cost involved in the GPRS upgrade process is that of replacing the circuit-switched core network connecting existing base stations with an IP-based backbone network for interfacing between the wireless system and the Internet. You can create an interface between a GPRS network and an IP network by using a GGSN. You can also use GGSNs to connect GPRS networks with legacy X.25 packet-switching networks.

Prospects

GPRS is viewed as an interim solution to give mobile users a measure of access to the Internet. The GSM Alliance, representing 400 GSM providers and their 250 million subscribers worldwide, is a driving force behind the move toward upgrading existing GSM systems to GPRS. As an example, AT&T Wireless plans to migrate its existing TDMA system (a 2G system based on IS-136) in several stages over the next few years, starting first with GPRS, a 2.5G upgrade, then Enhanced Data Rates for Global Evolution (EDGE), an IMT-2000 3G upgrade to GPRS, and finally to Universal Mobile Telecommunications System (UMTS) which will support 3G speeds of 2 megabits per second (Mbps).

In late 2000, a large cellular operator in Hong Kong SAR called Pacific Century CyberWorks (PCCW) launched a 20 kilobits per second (Kbps) GSM-based GPRS overlay, which, in order to access, subscribers need to upgrade their handsets to Motorola P7389i.

Other GSM operators around the world are involved in similar upgrades, with GPRS handsets becoming available from Nokia and other vendors. Lucent Technologies and Sun Microsystems are also working together to provide a platform for GSM upgrades to GPRS.

Notes

EDGE is almost identical to GPRS, the main difference being that EDGE uses a more efficient encoding scheme (8-bit phase shift keying or 8-PSK) which encodes three bits per symbol instead of the Gaussian phase shift keying (GMSK) mechanism of GSM (and also GPRS) that encodes only one bit per symbol. The result is that EDGE theoretically supports data transmission rates up to 513 Kbps, three times the maximum possible for GPRS. Real speeds for EDGE systems will be much lower, however, due to protocol overhead, error correction, and bandwidth throttling by providers. Although EDGE speeds are lower than the 2 Mbps limit intended for 3G systems by the IMT-2000 recommendations from the International Telecommunication Union (ITU), EDGE is still classified under IMT-2000 as a 3G system.

GPRS cannot be used to easily upgrade existing Code Division Multiple Access (CDMA) cellular systems, which are widely in use throughout North America and some other parts of the world. These systems are expected to migrate to Wideband CDMA (W-CDMA) instead, a 3G recommendation from the ITU that offers speeds up to 2 Mbps.

Gigabit Ethernet (GbE)

A form of Ethernet that operates at 1 gigabit per second (Gbps).

Overview

Gigabit Ethernet (GbE) is an evolution of standard Ethernet technologies that supports the transmission of data at 1 gigabit per second (Gbps) or 1000 megabits

per second (Mbps) over both fiber-optic cabling and copper twisted-pair cabling. GbE was developed to solve the problem of increasing congestion on local area network (LAN) backbones currently running Fast Ethernet, Fiber Distributed Data Interface (FDDI), and Asynchronous Transfer Mode (ATM). Because of its simplicity and throughput, GbE has become the dominant LAN backbone technology, relegating the slower FDDI to the legacy arena and pushing the complicated ATM back into the wide area network (WAN) environment where it originated. Because of its close similarities to other forms of Ethernet, GbE provides a smooth upgrade path from 10 megabits per second (Mbps) Ethernet and 100 Mbps Fast Ethernet.

The Gigabit Ethernet Alliance is an open forum that promotes cooperation and industry standards for GbE. The Alliance includes a number of prominent companies, including Cisco Systems, Intel Corporation, Sun Microsystems, Nortel Networks, and 3Com Corporation. GbE is standardized by the IEEE specifications 802.3z in 1998 and 802.3ab in 1999.

Uses

GbE's main application is for building high-speed backbones for LANs and campus networks. An example would be for high-speed switch-switch connections where you might connect two 100 Mbps switches with 1 Gbps uplinks to create Fast Ethernet islands joined by a GbE backbone. Alternatively, you could connect several 10/100 switches to one 100/1000 switch. For collapsed backbones, 1000BaseT copper interconnects are sufficient to join switches together, but for campus-wide distributed backbones, 1000BaseLX running over single-mode fiber supports the long distances needed to build such infrastructure. The problem is that many existing FDDI campus backbones use multimode fiber, and GbE does not operate over long distances on this type of fiber. This usually necessitates pulling new fiber to replace existing multimode fiber campus backbones with single-mode fiber to enable GbE to run over these backbones. Single-mode fiber is more expensive than the multimode type, and pulling fiber is an expensive process itself, so these costs generally add a significant amount to the process of converting legacy FDDI campus backbones to newer GbE ones. On the other hand,

upgrading switched Fast Ethernet backbones in small and mid-sized companies to GbE may simply be overkill. Overprovisioning of GbE is common by system integrators, and it provides small gains over existing Fast Ethernet networks with considerable added cost.

GbE is also finding an increasing place in server-switch connections for joining server farms to high-speed backbones. This configuration can theoretically provide users with 1-Gbps access to application or file servers, but there are limitations at present. The problem is that even with newer 1 Gbps network interface cards, most servers still cannot make full use of a gigabit link to a GbE switch. Various factors are at work here, including the existing 64-bit Peripheral Component Interconnect (PCI) bus being too slow to pump data out at gigabit speeds (the upcoming PCI-X standard may help here), hard disk subsystems being unable to keep up with the flow of data to and from the server (even 10,000 RPM hard disks cannot read/write at gigabit speeds), and the Transmission Control Protocol/Internet Protocol (TCP/IP) stacks of operating systems being unable to handle gigabit data transfer rates (though Microsoft Windows 2000 is a considerable improvement in this area over Windows NT). The bottom line is that aggregating two or three Fast Ethernet links is currently sufficient for handling data transfer to most Wintel servers and is a cheaper solution than adding a Gigabit network interface card (NIC) and connecting it to a Gigabit switch. This will probably change around 2002 as 64-bit Windows running on Itanium chips may finally perform to the point of needing a second Gigabit NIC to handle throughput, but keep your eyes on developments in hard disk technologies as their performance is usually the limiting factor or bottleneck in keeping file servers from pumping data at gigabit speeds.

Gigabit-to-the-desktop is a vision of deploying GbE end-to-end across a network, and involves installing 1 Gbps NICs into high-performance workstations to provide them with incredibly fast access to network servers. This is still more a dream than a reality, though, because such workstations suffer from the same limitations that were described for servers above, and even more so. The result is that deploying GbE end-to-end across a network generally results in only a marginal

improvement over Fast Ethernet in applications performance and greatly complicates the already difficult task of troubleshooting high-speed switched networks. In the old days of shared Ethernet networks, a “sniffer” could be connected to the main hub and traffic on the entire LAN could be analyzed—capturing and analyzing traffic on a switched LAN is much more complicated, and protocol analyzers operating at gigabit speeds are expensive. In any case, gigabit-to-the-desktop is still several years from everyday reality, and most desktop applications can achieve sufficient bandwidth using only Fast Ethernet.

Another hindrance to completely migrating a network’s infrastructure from Fast Ethernet to GbE over copper (1000BaseTX) is cabling. Although GbE can theoretically run over existing Category 5 (Cat5) cabling, such cabling usually has not been installed with the care and precision needed to support gigabit signaling speeds. Also, GbE over copper requires the use of all four pairs of wires, whereas some flavors of Fast Ethernet only needed two pairs of wires. As a result, corporate networks often need considerable rewiring to support GbE, and even new deployments using enhanced Category 5 (Cat5e) or Category 6 (Cat6) wiring require exceptional care in how they are installed to ensure that GbE will perform as expected.

Architecture

Like earlier forms of Ethernet, the GbE standards specify only the physical (PHY) layer and data-link layer of network operation and support any protocols running at higher levels. This means that upgrading from Ethernet or Fast Ethernet to GbE is relatively straightforward and only involves insuring that GbE supports the cabling media, cable lengths, and cabling topology. No changes need to be made to higher-layer protocols such as TCP/IP during such an upgrade (although sometimes such network layer protocols can be “tuned” to provide better performance in a GbE environment).

GbE uses the same connectionless datagram delivery services as earlier forms of Ethernet. It uses the same frame format as other forms of Ethernet and likewise supports both unicast, multicast, and broadcast frames. It can operate in both shared (half-duplex) and switched

(full-duplex) modes. GbE employs a line coding scheme called 8B/10B that packs 8 bits (1 byte) of data into 10 baud (symbols) for transmission, a system known as 1000BaseX. This means that in order to achieve a data transmission rate of 1 Gbps, a signaling frequency of 1.25 GHz is required. The 8B/10B encoding scheme for GbE was borrowed from Fibre Channel technologies. GbE actually borrows most of the characteristics of its PHY and data-link layers from the Fibre Channel's FC-0 and FC-1 sublayers, with the exception of using a signaling rate of 1.250 Gbaud instead of Fibre Channel's 1.0625 Gbaud.

GbE uses the same standard 802.3 framing structure as standard Ethernet, with frames between 64 and 1514 bytes in length and using the same 48-bit MAC addresses (jumbo frames up to 9000 bytes are also supported). It also supports the same Carrier Sense Multiple Access with Collision Detection (CSMA/CD) media access method supported by earlier versions of half-duplex Ethernet. To achieve the tenfold speed increase of GbE over Fast Ethernet while maintaining support for reasonably large networks, GbE makes some changes to the Ethernet MAC algorithm and how CSMA/CD operates. These changes are necessary because reducing the transmission time for a frame by a factor of 10 on an Ethernet network normally means that the size of the network (maximum distance between stations) would also decrease by the same factor.

One of the media access control (MAC) layer modifications introduced by GbE is called carrier extension, which involves extending the length of the carrier and slot times to pack out all frames to a minimum carrier length of 512 bytes to ensure that collisions can be properly detected and recovered from. In other words, the smallest possible frame (64 bytes) would have its carrier signal extended until it appears to the physical layer as 512 bytes in length. This is different from merely padding a 64-byte frame with an additional 448 bytes of junk to produce a 512-byte frame—instead, the carrier signal is extended for a time equivalent to 448 additional bytes, but the frame still appears to be 64 bytes in length from the point of view of layers above the MAC layer. As a result, if the frame is bridged from a GbE to a

Fast Ethernet network segment, for example, the frame remains 64 bytes in length on the Fast Ethernet segment, instead of 512 bytes if the frame were merely padded. Another MAC layer modification in GbE is support for frame bursting, which allows multiple short frames to be grouped in a way that it allows a station to take temporary control of the wire to send out a number of small packets in succession, arbitrating the signal for the channel only once. This second feature is optional but results in better performance in many situations.

Both of these modifications are done to enable shared half-duplex implementations of GbE to support a network diameter of up to 655 feet (200 meters), instead of the inadequately small 65.5-foot (20-meter) wide network that would result if CSMA/CD were implemented without these modifications. When implementing switched full-duplex GbE, CSMA/CD is not used and these issues are irrelevant because no collisions can occur.

GbE also supports several schemes for autonegotiation, allowing hubs, switches, routers, and NICs capable of supporting 100/1000 Mbps or even 10/100/1000 Mbps speeds.

Implementation

GbE can be implemented in four different PHY layer options, all of which support both half-duplex and full-duplex operation:

- **1000BaseCX:** Uses 150-ohm balanced twinax cabling or shielded twisted-pair (STP) cabling with a maximum link length of 82 feet (25 meters). This version is designed primarily for device clustering and is not much used.
- **1000BaseLX:** Uses both long wavelength transmissions over single-mode fiber-optic cabling supporting distances of 3 miles (5000 meters) over 10 micron fiber and also short wavelength transmissions over multimode fiber supporting distances of 1640 feet (550 meters) over both 62.5 and 50 micron fiber. The single-mode version is used mainly for long cable runs; for example, to connect LANs across a campus.

Gigabit Ethernet. Simple example of using a 100/1000 Mbps GbE switch.

- **1000BaseSX:** Uses short wavelength transmissions over multimode fiber-optic cabling. This version is used mainly for short cable runs of up to 1805 feet/550 meters (over 50-micron fiber) or 900 feet/275 meters (over 62.5-micron fiber) and is intended for connecting workgroup switches in a building to a GbE backbone switch.
- **1000BaseTX or 1000BaseT:** Uses twisted-pair Cat5 cabling (all four pairs of wires are needed) with a maximum link length of 328 feet (100 meters), giving a maximum network diameter of 655 feet (200 meters). It is intended mainly for connecting high-speed servers to GbE switches and for switch-switch interconnects in collapsed backbones.

Note that the distances specified above are for full-duplex operation only, because they are the inherent or physical distance limitations of the media for Gigahertz signaling. For half-duplex networks, the distance restrictions are more severe and depend on the round-trip propagation delay supported by the MAC

signaling method. For example, the maximum supported link length for 1000BaseLX and 1000BaseSX is only 364 feet (111 meters), well below the physical signaling distances supported by fiber medium.

Shared (half-duplex) implementations of GbE support only two simple topologies: a point-to-point connection between two stations and a star-wired topology with a hub (repeater) at the center, typically with 8, 12, or 24 ports on a hub. Cascaded hub topologies are not supported by shared GbE LANs, though some manufacturers sell stackable hubs whose backplanes can be connected to form a single collision domain. As a result of these topology restrictions, switched (full-duplex) implementations are much more common in real-world networks, and they support virtually any topology you can imagine as long as the length restrictions outlined above are adhered to (there are even ways around these length restrictions at times, as will be mentioned later).

Advantages and Disadvantages

Compared to other network backbone technologies, GbE has a number of distinct advantages. The most

obvious advantage over FDDI is the superior speed offered by GbE. The result is that GbE has pushed FDDI from the corporate mainstay it was in the mid-1990s to being legacy technology today that most enterprises are phasing out. Most corporate FDDI network backbones have now migrated to GbE, and the remaining ones are not likely to last beyond a couple of years as chip manufacturers for FDDI equipment stopped producing as of 2001.

G

GbE also has several advantages over ATM that make it the current favorite for enterprise network backbones. Most ATM backbones operate at 155 or 625 Mbps and fall short of the 1 Gbps for shared half-duplex GbE and 2 Gbps of switched full-duplex GbE. ATM is also more expensive and difficult to deploy and maintain than GbE. Most network architects can transition from Fast Ethernet to GbE technologies as easily as they previously moved from 10BaseT to Fast Ethernet, since the technologies are so similar. On the other hand, ATM still holds the superior hand in the WAN where it can run over Synchronous Optical Network (SONET) for thousands of miles and for delay-sensitive applications such as voice and multimedia where GbE still falls short, although new quality of service (QoS) mechanisms for Ethernet, such as DiffServ and 802.1p VLAN tagging, may help narrow the gap.

Upgrading a Fast Ethernet backbone switch to a GbE 100/1000-Mbps switch is straightforward and will enable you to connect high-speed server farms using GbE NICs. Benefits include increased throughput and performance, more network segments, more bandwidth per segment, and more nodes per segment.

Marketplace

The growth of GbE market in the last few years has been impressive, with GbE port module shipments reaching 4 million in 2000, a quarter of which were 1000BaseTX copper ports. For comparison, however, these port figures only represent 3 percent of the total market for all forms of Ethernet, but the figures for GbE are more than doubling each year.

GbE hubs (repeaters) are not common, but GbE switches and routers are made by a wide variety of vendors. A popular example is the Catalyst 3500 series of switches from Cisco, which have a 10 Gbps backplane that provides high performance, come in 12 and 24 GbE port configurations, and support both full-duplex and half-duplex operation even over copper. 3Com's SuperStack 3 switches are another good choice, with the 4900 series providing 12 copper or fiber gigabit ports for aggregation of Fast Ethernet workgroups. A typical scenario might be to connect a dozen 3300 series 10/100 switches using gigabit fiber uplinks to a core 4900 switch. Enterasys has GbE through its entire product line of switches and routers, and Foundry gigabit products are also popular in the enterprise.

GbE switches come in two basic types:

- **Backbone switches:** These generally have 8 or 12 copper or fiber GbE ports and one or two GbE uplinks and are used for building collapsed backbones for high-speed networks. A popular example is the 12-port AT-9006LX switch from Allied Telesyn International, which has a lower per-port price than many comparable switches. Other popular backbone switches for mid-sized networks include the Intel 480T, the Catalyst 4908 from Cisco, and the Summit5i from Extreme Networks.
- **Workgroup switches:** These can have 8, 2, 24, or even 48 Fast Ethernet 10/100 ports and up to four GbE uplinks, and they are used for building Fast Ethernet islands by uplinking many Fast Ethernet switches to a single workgroup switch. Galileo Technologies has managed to cram 48 autosensing 10/100 ports and two GbE uplinks into a 1U rack-mountable device, which is quite an engineering feat.

In the distributed backbone market, the 1805-foot (550-meter) limitation for GbE over multimode fiber can be overcome by a GbE extender such as Allied Telesyn's AT-EX1001SC/GM1, which allows GbE to run over multimode fiber to a distance of 1.25 miles (2 kilometers). Campuses needing to upgrade their old FDDI-based distributed backbones to GbE can save

money by using extenders like these instead of replacing existing multimode fiber with single-mode fiber.

Finally, network analyzers for troubleshooting GbE networks are available from Agilent Technologies (a spinoff from Hewlett-Packard), Network Associates, and Fluke Networks.

Prospects

GbE is here to stay. Most new enterprise networks being deployed these days are implemented with GbE backbones instead of FDDI or ATM (Fast Ethernet is still used for backbones in small to mid-sized companies). The only thing that can probably dethrone GbE is the emerging 10 GbE standard, an even faster version of Ethernet that finally discards the inefficient CSMA/CD media access method, operates instead only in switched full-duplex mode, and supports up to 40 kilometers (25 miles) using single-mode fiber. Meanwhile, prices per 1 Gbps port for GbE switches continue to fall, and even though the industry average was around \$1,000 per port at the end of 2000, there were some vendors offering switches with prices as low as \$300 per port. It will not be long until the price per port drops to the point where network architects may as well buy GbE switches instead of Fast Ethernet ones even if they achieve no immediate performance gains.

Another emerging use for GbE is as a transport for moving data between servers and storage area networks (SANs). GbE SANs encapsulate Small Computer System Interface (SCSI) traffic within Internet Protocol (IP) packets, making it possible to greatly extend the 165-foot (50-meter) limitation of SCSI and to locate SANs at remote data centers.

Gigabit in the metropolitan area network (MAN) is the latest development and provides an attractive alternative to telco T-carrier services to enterprises needing high-speed WAN connections. For more information on this exciting new technology, see the article “metropolitan Ethernet” elsewhere in this book.

Notes

By employing jumbo frames up to 9000 bytes in length, performance of gigabit server-switch connections can

generally be improved significantly, provided the hard disk bottleneck has not been reached.

Gigabit Interface Converter (GBIC)

A modular transceiver for Fibre Channel switches and other devices.

Overview

Gigabit Interface Converters (GBICs) provide network architects with flexibility in choosing different media options for gigabit-speed switches. They support a variety of different cabling options, including unshielded twisted-pair (UTP) and single-mode or multimode fiber-optic and copper Fibre Channel cabling. By simply plugging the appropriate GBIC module into a port on a Fibre Channel or Gigabit Ethernet (GbE) switch, a different media option can be easily configured for that port, providing flexibility for configuring switches according to need. This is accomplished by having the GBIC convert the signals in the connected media (for example, light signals on a fiber-optic cable) into electrical signals compatible with the 1000BaseX port on the switch. GBICs can also regenerate signals, allowing transmission to occur over distances of 62 miles (100 kilometers) or greater over long-haul single-mode fiber.

Marketplace

An example is 1000BaseT GBIC from Cisco Systems, which can be used to provide flexibility in cabling options for Cisco Catalyst 2900 and 3500 Series XL GbE switches. Cisco 1000BaseT GBICs come in a wide variety of transceiver configurations that support copper, long-haul and short-haul fiber, and backplane interconnects for stacking switches. They are also hot-swappable,

allowing cabling to be switched to different types on the fly in a simple plug-and-play fashion.

G.Lite

A splitterless version of Asymmetric Digital Subscriber Line (ADSL).

Overview

G.Lite is a form of ADSL that is targeted mainly for the residential Internet access market. G.Lite is easy to install—so easy that a home user can perform the installation, eliminating the need for a “truck roll” (technician visit) from the telco to the subscriber. This saves the telco considerable costs and allows them to pass this saving on to the subscriber. G.Lite was partly developed as a response to the challenge presented by cable modem technology, where subscribers can usually perform the installations themselves. G.Lite is intended to be a “plug and play” version of Digital Subscriber Line (DSL).

Like other forms of DSL, G.Lite connections are “always on”—once you turn your computer on, the connection is active and you can send or receive e-mail or browse the Web without having to dial up a connection. G.Lite is slower than regular ADSL and supports maximum downstream transmission of 1.536 megabits per second (Mbps) and upstream 384 kilobits per second (Kbps), depending on the implementation.

G.Lite is sometimes called DSL Lite or Universal ADSL, but the International Telecommunication Union (ITU) has endorsed the term *G.Lite* as official nomenclature for this technology under the G.992.2 standard. Commercial rollouts of G.Lite began in 1999, and the service is gaining popularity among DSL providers.

Implementation

G.Lite is sometimes referred to as splitterless ADSL because a splitter is not required at the customer premises to separate the voice and data signals being carried over the phone line. This is different from ordinary

ADSL, which uses a splitter to separate the baseband analog Plain Old Telephone Service (POTS) voice channel from the upstream and downstream DSL simplex bearer signals. The splitter protects the ADSL signal from variations in impedance of the POTS signal and from dial tones and other forms of interference. Likewise, the splitter protects the POTS signal from interference due to intermodulation of the ADSL tones. In ordinary ADSL, a splitter must be installed at both the customer premises and the telco’s central office (CO). G.Lite gets around the need for a splitter at the customer premises by incorporating a number of advanced signal processing techniques that help keep the bit error rate (BER) within reasonable tolerances. These advanced techniques include forward error correction, trellis encoding, and interleaving.

To use G.Lite, the customer obtains a G.Lite modem from the DSL provider and simply connects it to her computer and phone line. No second phone line or other form of rewiring of the customer premises is required, since G.Lite uses the existing local loop connection to the customer premises. Customers can make phone calls or send faxes while connected to the Internet over their G.Lite connection.

Notes

The quality of a G.Lite connection to your home can suffer if you have a large number of RJ-11 phone jacks installed. This is because each phone jack acts as a bridged tap that is run off the main phone line as a parallel connection. Signals traveling along your phone line can reflect off these jacks and affect the overall reliability of your G.Lite connection. Also, the farther your home is from the telco CO, the less bandwidth might be available for your G.Lite connection.

Global.asa

A file that contains global information for Active Server Pages (ASP) applications.

Overview

The Global.asa file is used to manage functions common to all users of an ASP application. Specifically, a Global.asa file includes

- Four event procedures common to all users of an ASP application, namely `Application_OnStart`, `Application_OnEnd`, `Session_OnStart`, and `Session_OnEnd`.
- Object declarations (using `<OBJECT>` tags) for defining application-level and session-level objects, variables, and event handlers.
- Type library declarations for COM components used by the application.

Global.asa files should not generate or contain any content that is visible to a client Web browser—`Asp.dll` will simply ignore any Hypertext Markup Language (HTML) placed in the Global.asa file. Furthermore, you can have only one Global.asa file per ASP application, and the file must be located in the root virtual directory of the application.

Notes

If your Global.asa file generates an error, you should ensure that any object declarations within the file have application-level or session-level scope, that any script in the file is enclosed within `<SCRIPT>` tags, and that any `<OBJECT>` tags are placed outside of `<SCRIPT>` tags.

global catalog

A Microsoft Windows 2000 or Windows .NET Server domain controller that contains a read-only, partial replica of information from all domains in a forest.

Overview

The global catalog resides on a selected group of domain controllers in your Windows 2000 or Windows .NET Server enterprise called global catalog servers. The global catalog is automatically created the first time you run the Active Directory Installation Wizard and is installed on the first domain controller in the root domain by default. Other domain controllers must then

be manually designated as global catalog servers by using the administrative tool Active Directory Sites and Services. The Active Directory directory service replication process then automatically maintains the contents of each global catalog server.

In a geographically distributed enterprise, each physical site should have at least one domain controller to speed network traffic. Most Active Directory–related traffic is the result of queries on Active Directory, so the domain controller for small sites should also be configured as a global catalog server. This will reduce traffic over wide area network (WAN) links to other sites by allowing the global catalog server to locally resolve queries for information on directory objects from other domains.

Every Active Directory object in the entire enterprise is represented in the global catalog, but only a subset of the attributes of each object is stored in the catalog. The properties represented are those most likely to be used as search attributes, such as the user's first or last name. However, administrators can specify storing additional object attributes in the catalog if desired. You can modify which attributes are represented for objects in the global catalog by editing the schema of Active Directory, but you must do so with care.

Uses

The global catalog enables users to easily locate objects in any domain with maximum speed and minimum network traffic. In effect, the global catalog acts as a kind of index for looking up objects stored in Active Directory anywhere on your network. Having the global catalog store only a subset of an object's attributes in Active Directory improves the response time for performing search queries on Active Directory. You can search the global catalog for Active Directory objects by using the Find dialog box in Active Directory Users and Computers. Note that the global catalog also includes the access permissions for directory objects, so if you search for an object and it does not show up, you probably do not have permission to access the object.

The global catalog also has another important function—in native-mode domains, users require access to a global catalog server in order to log on to the domain. If

no global catalog server is in the local site, a global catalog server in a remote site may be used. If all global catalog servers are down in a native mode domain, users can only log on using their cached user credentials. An exception to this is that members of the Domain Admins group can log on to native domains even when no global catalog server is available.

global catalog server

A Microsoft Windows 2000 or Windows .NET Server domain controller that contains a copy of the global catalog.

Overview

Global catalog servers let users search for objects located anywhere in a forest and enable users to log on to the domain in native-mode networks. Information stored on global catalog servers is updated each time Active Directory directory service performs its directory replication process.

Global catalog servers should be located appropriately so that queries on Active Directory can be performed effectively. Ideally, you should have at least one global catalog server in each site within the enterprise. However, in a multidomain environment, the replication traffic generated by maintaining these servers can be a burden on overall network traffic, especially if slow wide area network (WAN) links are involved. In this case, consider placing your global catalog servers as follows:

- Place several global catalog servers in each major site where large numbers of users and resources can be found.
- Place a global catalog server at each small site where there are significant numbers of users and resources or where the WAN connection to major sites is slow.

global group

A type of security group in Microsoft Windows NT, Windows 2000, and Windows .NET Server.

Overview

In Windows NT, global groups are used to simplify administration of user accounts by organizing them into groups. For example, you can use them to group users by function (such as the Accountants global group), by location (such as the Third-Floor global group), or by some other criteria. By contrast, local groups are designed to provide users with permissions for accessing network resources and rights for performing system tasks.

Global groups can contain only global user accounts from their own domain. They cannot contain global user accounts from other domains, nor can they contain other groups. Global groups are created on domain controllers and are stored within the Security Accounts Manager (SAM) database.

In Windows 2000 and Windows .NET Server mixed-mode domains, global groups operate much the same as in Windows NT, and they can be granted permissions on resources in any domain in the current forest. In native mode, however, global groups can contain both user accounts and global groups from the same domain.

global load balancer

A hardware-based or software-based solution that can direct requests for Web content to multiple geographical locations where the content is stored.

Overview

An example of using global load balancers might be for an e-business that has many data centers scattered around the world to use global load balancers to direct Web customers' traffic to centers that can provide the fastest response time for each customer's location. If a data center goes down as a result of a power outage or some other condition, traffic to that site can be transparently redirected to other sites. The overall effect of implementing global load balancers in an e-business enterprise is an increase in reliability and performance from the customer's point of view.

Implementation

Global load balancers essentially act as intelligent Domain Name System (DNS) name servers, performing name lookups for Uniform Resource Locators (URLs) and directing requests to the most appropriate Internet Protocol (IP) addresses. The five criteria listed below are typically used to determine which address to forward a request to. (Note that not all global load balancers support all of five of these criteria.)

- Proximity of the site to the client, usually measured in router hops and established by using the Border Gateway Protocol (BGP), Internet Control Message Protocol (ICMP), or User Datagram Protocol (UDP)
- Latency (the overall response time of the site), which is usually determined by pinging the site and calculating the delay
- Server load (how busy the site is and how much capacity the server has for responding to clients)
- Server health (whether the site is up and what its CPU and connection load are)
- Packet loss (the average quality of the Transmission Control Protocol [TCP] connection to the site), which is established by using ping

Of course, the DNS standard itself has built-in load balancing in the form of round-robin DNS. If multiple IP addresses are mapped to the same domain name, clients requesting the domain are directed to each IP address in a round-robin fashion. However, this rudimentary load-balancing scheme does not take into account such factors as which IP address belongs to the nearest host, the relative capability of the hosts to respond to requests, the availability of hosts, and so on. This is where global load balancers come in—they take over the role of authoritative name server for a company's domain.

Global load balancers come in three varieties:

- Layer 4 switches or routers with built-in support for global load balancing. Many Layer 4 switches and routers support some form of local load balancing, and software upgrades might be available that add such support. These switches tend to perform faster

than appliances or software because they use hardware for packet forwarding and use software for routing purposes only. However, they also tend to be the most expensive solution.

- Network appliances, which are essentially self-contained, stripped-down servers running global load-balancing software on top of operating systems optimized for this particular function.
- Software that can run on standard servers running Microsoft Windows 2000, Windows NT, or UNIX that enables the servers to function as global load balancers. If you use this solution, be sure that your server is dedicated to running this software and does not run any other applications.

Global load balancers talk only to the local DNS server configured for the client, not to the client itself. This works well, except when mobile users travel to other cities and use their laptops to try to access the site. In this situation, if the client is still using a preconfigured DNS server at the home location, the global load balancer thinks that the client is still there as well. Also, once a DNS-based global load balancer has directed a client to the appropriate site or server, it is no longer involved in the client's session and cannot tell whether the server goes down or whether some problem occurs with the connection.

For this reason, some global load balancers also use Hypertext Transfer Protocol (HTTP) redirects to masquerade as the target site and redirect HTTP requests to different servers. The client actually talks to the load balancer itself, and performance is faster than using DNS because fewer TCP connections are required. If the client's connection to the server is interrupted, the global load balancer can redirect the client to a different server with minimal interruption. The downside of using HTTP redirects is that they work only with HTTP and not with other Internet protocols, such as File Transfer Protocol (FTP) or Network News Transfer Protocol (NNTP), or with streaming multimedia. This can be a limitation if your e-business delivers this type of content to the customer.

Other mechanisms can be used to perform global load balancing, including cookie-based and proprietary schemes. Windows NT 4, Enterprise Edition, provides a load-balancing service called Windows NT Load Balancing Service (WLBS). This IP load-balancing service employs a fully distributed clustering design that is ideal for creating highly available and scalable IP-based services such as Web, virtual private networking (VPN), streaming media, and proxy services.

globally unique identifier (GUID)

In Microsoft Corporation operating system platforms and programming, a 128-bit value based on time and space that can be used to uniquely identify a component.

Overview

Globally unique identifiers (GUIDs) are employed by the Component Object Model (COM) to uniquely identify classes and interfaces so that naming conflicts will not occur. A GUID is virtually guaranteed to be unique across all systems at any time. For example, every object, class, and attribute in Active Directory directory service is assigned a unique GUID when it is created. The GUID of an entity in Active Directory never changes, even if the entity itself is renamed or moved to another location. The GUID acts as a kind of permanent name for the entity within the directory to ensure that it can be positively identified when needed.

Microsoft BackOffice products such as Exchange Server and SQL Server also use GUIDs to uniquely tag objects. For example, the information store in Exchange Server has a base GUID that is used to generate individual GUIDs for all messages, attachments, and folder contents kept in the store. If you restore the information store from a backup, you need to run the command `isinteg-patch` before restarting the information store to change the base GUID. Running this patch ensures that new objects created in the information store do not accidentally end up with GUIDs that are identical to those

of objects already existing in the information store. This could cause inconsistencies in the information store database.

Notes

You can also manually generate GUIDs for components using the console-based `Uuidgen` utility or the Microsoft Windows-based `Guidgen` utility in Microsoft Visual C++.

Global System for Mobile Communications (GSM)

A second-generation (2G) digital cellular communications technology popular in Europe, Asia, and other parts of the world.

Overview

Global System for Mobile Communications (GSM) is the only truly worldwide cellular communications system. More than 400 different GSM carriers have implemented GSM systems in more than 200 countries and regions, and there are more than 250 million subscribers worldwide (all other cellular systems combined account for only 150 million subscribers worldwide).

GSM cellular supports voice communications rivaling the analog Advanced Mobile Phone Service (AMPS) system in speech quality. GSM also supports other services, including

- Group 3 fax (ITU recommendation T.30)
- Circuit-switched and packet data communications at speeds up to 14.4 kilobits per second (Kbps)
- Short Message Service (SMS), a two-way paging service that supports store-and-forward delivery of short text messages up to 160 characters in length.

GSM also supports other services including caller ID, call waiting, call forwarding, and conference calling.

GSM operates in different frequency bands and is described by different names depending on the band used, including the following:

- **GSM 900 or simply GSM:** This is the original GSM system that began operation in 1992.
- **GSM 1800 or PCN (Personal Communications Network):** This is a high-frequency version of GSM found in parts of Europe and gradually becoming the standard there.
- **GSM 1900 or PCS (Personal Communications System):** This is the counterpart of GSM 1800 in the United States and Canada.

History

GSM began as an initiative of the Conference of European Posts and Telegraphs (CEPT) to develop a pan-European digital communications system that would allow users to roam between different countries and regions with no interruption in service. Work on the new standard was begun in 1982 by a body called Groupe Spéciale Mobile, which gave the technology its acronym, GSM (later on GSM was changed to mean Global System for Mobile Telecommunications). GSM standards development was turned over to the European Telecommunications Standards Institute (ETSI) in 1989.

GSM was deployed in several phases, starting with GSM Phase 1, which was first commercially deployed in 1991 and which supported call forwarding, global roaming, call barring, and similar features. These initial 900-megahertz (MHz) GSM systems spread rapidly to 22 different countries and regions by 1993. GSM Phase 2 added additional features such as short message service, call holding, call waiting, caller ID, multiparty calling supporting up to five parties per call, and mobile fax and data services. GSM Phase 2+ deployments currently underway include support for data transmission at 64 Kbps and higher, packet radio, virtual private networks, enhancements to the Subscriber Identity Module (SIM) card, higher spectral efficiency, integration with satellite links, and even GSM services in the local loop.

Architecture

GSM uses a combination of Frequency Division Multiple Access (FDMA) and Time Division Multiple Access (TDMA) media access control methods to provide full-duplex communication. In the 862-to-960-MHz World Association of Radio Communications

(WARC) portion of the electromagnetic spectrum, GSM communicates using two separate frequency bands:

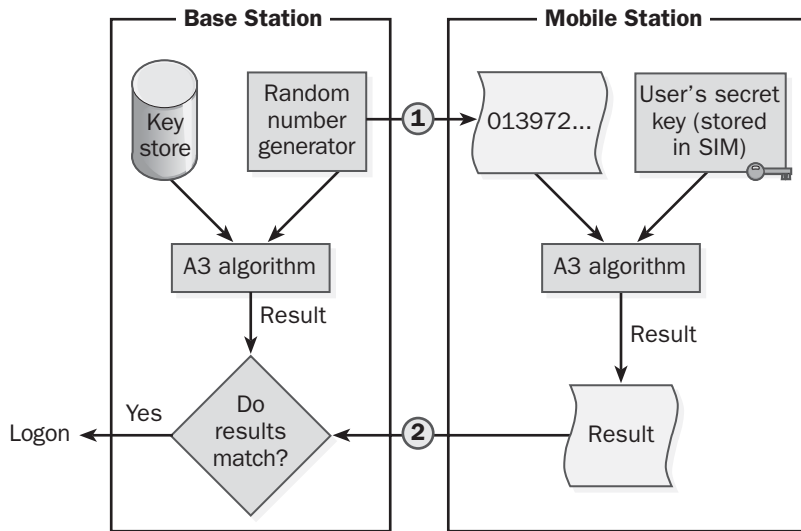

- The 890- to 915-MHz band for mobile-to-base (uplink) communication
- The 935- to 960-MHz band for base-to-mobile (downlink) communication

Carrier signals are spaced 200 kilohertz (kHz) apart within these bands based on frequency-division multiplexing (FDM) to provide 124 pairs of superchannels (carriers). Each superchannel is then subdivided using time-division multiplexing (TDM) into eight traffic channels (time slots), some of which are used as communications channels and others as control channels. Each communications channel carries either digitized voice at 13 Kbps or data at either 9.6 or 14.4 Kbps. Altogether GSM provides 992 full-duplex channels for voice communication. By comparison AMPS cellular systems, which also use TDMA, employ three time slots instead of eight.

A single GSM time slot can carry a payload of 156 bits and is 0.577 microseconds in duration, a time interval called the burst period. This suggests that the total data carrying capacity of GSM could theoretically be 33.8 Kbps, but much of this is used for protocol and error correction overhead, reducing the maximum possible data transmission rate to only 14.4 Kbps. The short duration of a GSM time slot also restricts the maximum distance at which a GSM phone can communicate with its base station to about 22 miles (35 kilometers) regardless of the power used.

Power classes for GSM mobile units range from 0.8 through 2.0 watts transmission power for handsets to 8 through 20 watts for vehicle-mounted units. Approximately half of a GSM transmission consists of overhead for signaling, such as synchronization and error handling. Such high overhead is typical in cellular phone systems and is necessary—not so much because of external interference of buildings and other structures, but because of internal interference due to crosstalk between channels and across cell boundaries.

Global System for Mobile Communications (GSM). The authentication process for GSM.

Implementation

A basic GSM communications system consists of three parts:

- Mobile station (MS):** This is a cellular phone or vehicle-mounted phone used for sending and receiving calls. The MS also contains the user's SIM, a small "smart card" about the size of a postage stamp that is issued when a user subscribes to a GSM service. The SIM contains a unique number called an International Mobile Subscriber Identity (IMSI) that uniquely identifies the MS, the user's private key for encrypting transmissions, and billing information, such as the subscriber's address. The MS itself is uniquely identified by a number called an International Mobile Equipment Identity (IMEI), and the IMEI and IMSI are independent of each other. When a user moves from his home location to one where a different GSM system is used, the user can simply remove the SIM from his own GSM phone and install it in a GSM phone rented from a service in that location.
- Base station subsystem (BSS):** This is a fixed radio transmitter that provides coverage for a specific cell and handles call setup and tear down for mobile stations in the area.

- Mobile switching center (MSC):** This is a switching center that coordinates the operation of all BSSs in its coverage area, coordinates billing for subscribers, handles roaming and handoffs between cells, and provides gateway connectivity with the Public Switched Telephone Service (PSTN) or Post, Telephone, and Telegraph (PTT) land-based telephone system.

GSM communications are secured by employing key-based encryption for authentication traffic (and optionally for data transfer as well). The diagram shows the process that occurs when a mobile user wants to place a call. When the user dials a number, the mobile unit connects with the base station requesting authorization. The base station generates a random number and transmits it to the mobile unit, which then combines the random number with the owner's secret key stored in the phone's SIM by using a secret ciphering algorithm called A3. The result of this process is transmitted to the base station. Meanwhile, the base station, which has the private keys for all its subscribers stored in a database, follows the same steps, using the A3 algorithm to combine the generated random number with the caller's private key. The result is compared with the result transmitted by the user. If the two results agree, the user is logged on to the

system. Encryption of message traffic is similar to encrypted authentication, except that each transmitted frame is encrypted using a different random number. This makes encrypted GSM messages extremely difficult to crack, so much so that some countries and regions prohibit GSM providers from encrypting user messages!

Marketplace

Although GSM is the dominant cellular communications system in Europe and a major player in other parts of the world, such as Asia and the Pacific Rim, it ranks a distant third in North America behind the popular Code Division Multiple Access (CDMA) digital cellular systems such as Sprint PCS and behind Time Division Multiple Access (TDMA) systems best represented by AT&T Wireless Services and SBC Communications. This is changing, however, as U.S. GSM carriers such as VoiceStream Wireless Corporation (now owned by Deutsche Telekom) expand their coverage across areas connecting urban centers, especially in California, the Eastern seaboard states, Florida and the South, and the Texas-Minneapolis corridor.

With interoperability between these competing systems being a major issue for U.S. subscribers needing to travel abroad, QUALCOMM, the company behind CDMA cellular systems, has announced it plans to develop a chip that will enable cellular phones to work with both CDMA and GSM systems.

Prospects

GSM has fared well as a global standard communications technology apart from garnering little support in the United States. Initiatives are underway to enhance this 2G system into one capable of carrying data at speeds of 64 Kbps and higher. Two such upgrades are the General Packet Radio Service (GPRS) and High Speed Circuit Switched Data (HSCSD), both of which operate by multiplexing GSM's existing TDM slots. These 2.5G initiatives are stepping stones toward the next generation high-speed third-generation (3G) broadband cellular systems that are just beginning to appear in parts of the world.

Notes

GSM has a counterpart service called Digital Communication Service (DCS) that works in essentially the

same way as GSM, except at a higher 1.8-gigahertz (GHz) frequency band. DCS provides a total of 2992 channels for voice communication. One advantage DCS has over GSM is that it uses much lower power levels for mobile units, ranging from 0.25 to 1.0 watts transmission power.

global user account

A Microsoft Windows NT account that has a domain-wide scope.

Overview

In Windows NT, global user accounts are stored in the Security Accounts Manager (SAM) database on domain controllers. You can create them using User Manager for Domains, a Windows NT administrative tool. Global accounts allow users to take full advantage of the Windows NT Directory Services (NTDS). Users who have global accounts can access resources anywhere in the domain, provided they have permissions for those resources.

The other type of user account in Windows, the local user account, exists only within the directory database of the machine on which it is created. Use only global accounts for users when implementing Windows NT domains as your security model. User Manager for Domains creates global accounts by default.

Notes

In Windows 2000 and Windows .NET Server, global user accounts are instead called domain user accounts and they are managed using the Active Directory Users and Computers snap-in for the Microsoft Management Console (MMC).

GNOME

Stands for GNU Object Modeling Environment, a graphical desktop for UNIX and Linux platforms.

See: *GNU Object Modeling Environment (GNOME)*

GNU General Public License (GPL)

The open source licensing scheme of the Free Software Foundation (FSF).

Overview

The GNU Project was started in 1984 with the aim of developing a UNIX-like operating system that could be freely distributed. The acronym GNU itself recursively stands for GNU's Not UNIX (recursion is a feature of the UNIX operating system). The GNU General Public License (GPL) allows developers to freely copy and make changes to software as long as they provide the source code freely upon request and do not add any additional copyright restrictions to the modified software.

GPL is the licensing scheme used in all distributions of Linux, the popular free operating system developed by Linus Torvalds. The GNU gcc compiler is also the only C compiler that can be used to compile the Linux kernel. GPL forms the basis for licensing much of the free software that drives the Internet. GPL has also been chosen by Sun Microsystems as the licensing scheme for its free StarOffice suite of business applications.

GNU Object Modeling Environment (GNOME)

A graphical desktop for UNIX and Linux platforms.

Overview

GNU Object Modeling Environment (GNOME) is an open-source graphical user interface (GUI) developed by the GNOME Foundation under the GNU General Public License (GPL) licensing scheme. The GNOME Foundation was modeled after the Apache Foundation and includes such members as the Free Software Foundations (the originators of GPL), IBM, Hewlett-Packard, Compaq Computer Corporation, Sun Microsystems, Red Hat, and many others.

GNOME's purpose is to make UNIX and Linux platforms easier to use. GNOME is a highly configurable windows-based user environment that includes a desktop with application icons, a status panel, a set of tools, and other elements. The GNOME session manager allows a user's desktop settings to be maintained across user sessions.

Prospects

A competing open-source alternative to GNOME is the K Desktop Environment (KDE) developed under the auspices of the KDE League. KDE has many supporters, but GNOME is backed by industry heavyweights and has been selected by Hewlett-Packard as the standard graphical user interface for HP-UX and by Sun as the GUI for Solaris.

Gopher

A legacy Internet protocol used for distributed storage of documents.

Overview

Gopher is similar to another Internet protocol, File Transfer Protocol (FTP), because it remotely accesses files over a Transmission Control Protocol/Internet Protocol (TCP/IP) internetwork such as the Internet. But although an FTP site exists on only one server and there can be many different FTP sites, there's really only one distributed Gopher file system. The Gopher file system is a single collection of all Gopher servers in the world (although private Gopher subnetworks could also exist).

Gopher was popular in the late 1980s and early 1990s as a mechanism for storing and disseminating information across the Internet, especially for libraries and universities, but it has fallen out of favor because of the rising popularity of the World Wide Web (WWW). Not many Gopher servers still work, and most of them are not regularly updated with new information.

Gopher. The simple interface of the legacy Gopher protocol.

Implementation

Any Gopher server can act as a logical root of the hierarchical Gopher distributed file system. To access a file or document, a person using a Gopher client (a standard Web browser such as Microsoft Internet Explorer will do) types the Uniform Resource Locator (URL) of an accessible Gopher server. For example, `gopher://gopher.tc.umn.edu` takes the user to a Gopher server for the University of Minnesota (where Gopher originated). The Gopher file system is presented as a series of folders, each of which can contain

- Additional folders
- Individual documents
- Links to other Gopher servers (displayed as folders)

Users then work their way down the “gopher hole” (to use the metaphor) until they locate the document they want, and then they display or download it. They can also use a search tool developed at the University of Nevada called Veronica (Very Easy Rodent-Oriented Netwide Index to Computerized Archives) to perform keyword searches to locate documents on the world-wide Gopher network.

grep

Stands for global regular expression print, a powerful UNIX command.

Overview

Grep lets you search a file or multiple files for a specific pattern or string of characters and, if desired, replace it with a different string. Grep is also useful for searching for specific entries in text files such as log files, UNIX system error logs, or C program code files.

You can use wildcards and other meta-characters to perform complex search and replace operations with grep. The output of grep is a display of each line of the file that contains the desired character string.

Examples

Typing `grep 'a[b-f]' log.txt` searches the text file called `log.txt` for any lines that contain the character `a` immediately followed by `b`, `c`, `d`, `e`, or `f`.

Notes

Shareware versions of the grep utility are available from third-party vendors for Microsoft Windows platforms. Grep can also be combined with other UNIX commands in scripts that can perform more complex search functions. For example, you can pipe the output of a verbose command into grep to display a more selective form of output.

ground loop

A condition created when two or more parts of a network are grounded at separate points, causing a voltage difference between connected networking components.

Overview

Voltage differences between different parts of a computer network typically occur because of nonuniformities in the electrical characteristics of the grounding at different locations. For example, consider two computers that are located some distance apart and are connected by coaxial cabling. Each device is also connected to the earth by the ground wire of its AC power cable, but the two devices are plugged into different power outlets. These power outlets are connected to different parts of your building's electrical distribution system, and these different parts are under different loads (have different currents being drawn from them by different configurations of devices). Thus they provide slightly different voltages.

You might also find slight differences in the ground potential at the two locations. These voltage differences can cause currents to be induced through the shielding of the network cabling, and these currents can be large because of the cable's low resistance. Large pulses of current can occur when other devices on the power circuits are switched on or off abruptly. This situation can be potentially damaging to sensitive networking components and might cause them to reset or lock up.

Implementation

You can prevent ground loops in two main ways:

- By using nonconducting fiber-optic cabling instead of copper cabling, especially for longer cable runs
- By employing opto isolators or isolation transformers to break electrical connections between networking components

One might think that you could eliminate ground loops entirely by not grounding networking equipment, but this is wrong for several reasons. Ground connections are essential for electrical equipment to ensure their safety in the case of a short, and all electrical equipment should be properly grounded to ensure against shock hazard. Grounding also reduces noise due to electromagnetic interference (EMI) that can affect the perfor-

mance of hubs, switches, and cables. Noise can result in corrupted packets leading to retransmissions that eat up network bandwidth, and grounding equipment properly can reduce such noise and boost throughput.

Notes

Ground loops are especially problematic with serial connections such as RS-232 because cables using this interface have a second signal ground path between the devices. Ground loops can also be a problem with shielded cabling such as shielded twisted-pair (STP) cabling or coaxial cabling. These loops will occur if the cable's shielding is grounded by a direct connection to the chassis of the devices, because this provides a second ground path between the devices in addition to that produced by the ground portion of the AC power connection. The resulting current loops can build up until they are potentially damaging to the connected equipment. To prevent such damage, the shielding in a shielded cable should be grounded only at one end of its connection. Finally, when grounding a metal rack or cabinet that houses networking equipment, you should ground it using the same AC power cable ground connection that you used for the equipment itself. Note that ground loops are not a significant problem with unshielded twisted-pair (UTP) cabling because the wiring is transformer-isolated in the hub and network interface card (NIC) connections.

group

A collection of user accounts.

Overview

Groups simplify the task of network administration by allowing administrators to group similar user accounts together in order to grant them similar rights and permissions. In Microsoft Windows 2000 and Windows .NET Server, there are two types of groups:

- **Security groups:** Can contain members and can be granted permissions in order to control user access to network resources. Security groups can contain users, other groups, and even computers.
- **Distribution groups:** Used for nonsecurity functions, such as grouping users together to send mass

e-mail. Unlike security groups, these groups cannot be used to control user access to network resources.

In Windows NT there is only one type of group, which is equivalent to security groups in Windows 2000 and Windows .NET Server.

Implementation

In Windows 2000 and Windows .NET Server, you create groups using the Active Directory Users and Computers console, and these are stored as group objects within Active Directory directory service. In Windows NT, you create groups using User Manager for Domains, and they are stored in the Security Accounts Manager (SAM) database. Users can belong to multiple groups at the same time. A group does not actually contain its member user accounts; it is merely a list of user accounts.

The scope of a group is the portion of the network where the group can be granted rights and permissions. For example, a group whose scope is global can be granted permissions to resources in its own domain and to resources in trusting domains. On the other hand, a group whose scope is local can be granted permissions to resources only on the machine where it was created. In Windows 2000 and Windows .NET Server, there are three levels of scope for security groups:

- **Universal groups:** Can contain members from any domain and can be granted permissions to resources in any domain in the current domain forest. Universal groups can contain user accounts, global groups, and universal groups from any domain in the current forest. Note that you can create universal groups only when the domain is in native mode and not in mixed mode.
- **Global groups:** Can contain members only from their own domain but can be granted permissions to resources in any trusting domain. When the domain is in native mode, global groups can contain user accounts and global groups from the same domain. When the domain is in mixed mode, these groups can contain only user accounts.
- **Domain local groups:** Can contain members from any domain but can be granted permissions only to resources in their own domain. However, unlike the local groups of Windows NT, a domain local group

can be granted permissions to resources on all servers (both the domain controllers and member servers) in its domain. When the domain is in mixed mode, domain local groups can contain user accounts and global groups from any domain in the forest. When the domain is in native mode, they can also contain domain local groups from their own domain and universal groups from any domain in the forest.

On Windows 2000 and Windows .NET Server member servers and client computers and Windows XP machines, you can also create a fourth scope of group called a local group, one that exists only within the local security database of the machine on which it is created. Local groups in Windows 2000, Windows .NET Server, and Windows XP are similar to local groups in Windows NT. They can contain user accounts that are local to the machine and user accounts and global groups from their own domain. A local group can be granted permissions only to resources on the machine where it was created. You use Local Users and Groups, a snap-in for Microsoft Management Console (MMC), to create local groups on a machine.

Windows NT groups have only two levels of scope:

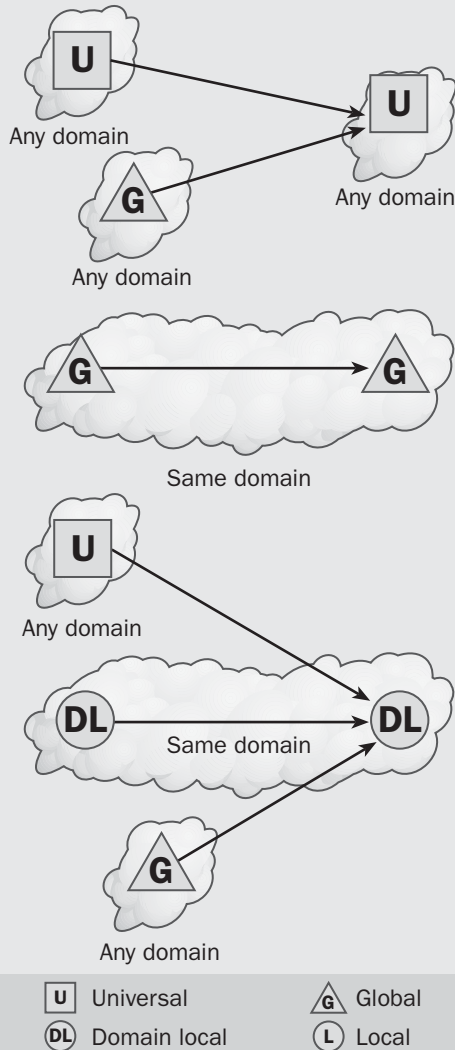

- **Global groups:** A global group can be granted permissions to resources in its own domain and to resources in trusting domains. A global group can contain user accounts only from its own domain. Global groups are created on Windows NT domain controllers and exist in the domain directory database.
- **Local groups:** A local group created with Windows NT Workstation can be granted permissions only to resources on the machine where it was created. A local group created with Windows NT Server (on a domain controller) can be granted permissions only to resources on the domain controllers of its own domain. A local group can contain user accounts and global groups both from its own domain and from trusted domains. Network administrators of enterprise-level Windows NT networks can use a resource-access strategy called AGLP (Accounts are organized by placing them in Global groups, which are then placed in Local groups that have appropriate Permissions and rights assigned to them) to plan and implement local groups in their network.

Nesting of groups in Windows NT

Nesting of groups in Windows 2000 and Windows .NET Server

In Windows 2000 and Windows .NET Server, you can change the scope of a group if you want (you cannot do this in Windows NT). For example,

- Global groups that are not members of other global groups can be converted to universal groups.
- Domain local groups that do not contain other domain local groups can be converted to universal groups. Do this if you want to enable users in other domains to access resources that have been made accessible to the domain local group under consideration.

Groups can also be nested by adding groups to other groups, with certain restrictions. For example, in Windows NT a local group can contain global groups (but not other local groups) as members, but a global group can contain only users as members, not other global or local groups. With Windows 2000 and Windows .NET Server, the nesting of groups is more complicated, as shown in the diagram. Furthermore, when running Windows 2000 or Windows .NET Server in native mode, you can nest groups inside groups to any level, although nesting to one level is the recommended practice for effective administration.

Notes

If your Windows 2000 or Windows .NET Server network has a single domain, use global groups and domain local groups to grant permissions to network resources. Create global groups according to function, add users to the global groups, create domain local groups according to groups of common resources, assign permissions to the domain local groups, and finally, place the global groups in the appropriate domain local groups. If you have a domain tree, use global and universal groups instead in a similar administrative approach.

On high-speed Windows 2000 and Windows .NET Server networks, using only universal groups simplifies network administration. But if you have slower wide area network (WAN) links within your enterprise, using global and domain local groups can reduce the size of the global catalog at each site and significantly reduce the WAN traffic required to keep the global catalog current. Using global and domain local groups further reduces WAN traffic by reducing the size of users' security tokens.

Group Policy

A feature of Microsoft Windows 2000, Windows XP, and Windows .NET Server that simplifies management of user and computer settings.

Overview

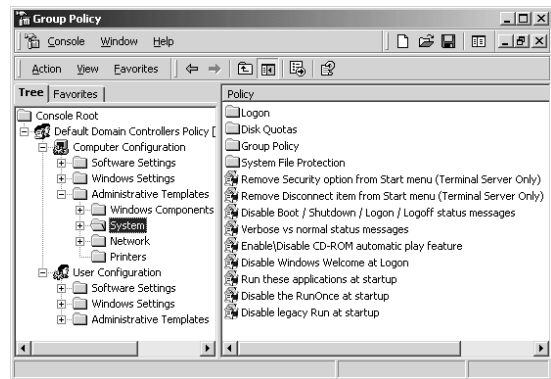

Group Policy enables administrators of Windows 2000 and Windows .NET Server networks to define policies that manage the environment of users and computers. A typical use for group policies is to enforce a written company policy across all users in a specific site or domain. Group policies can be used to simultaneously configure the desktop working environments for different groups of users, but they have many other uses as well. For example, group policies can be used to do the following:

- Manage applications—for example, by configuring policies to allow users to install applications published in Active Directory directory service or to automatically install or upgrade applications on their machines
- Redirect folders from the Documents and Settings folder on a user's local machine to a share on the network
- Assign scripts for startup, shutdown, logon, and logoff events
- Manage security—for example, to control users' access to files and folders, control user logon rights, and configure account lockout restrictions
- Manage software—for example, to configure user profiles such as desktop settings, Start menu, and other common settings

Implementation

Group policies can be assigned to domains, sites, or organizational units (OUs) and apply to all Active Directory objects (users, computers, printers, and so on) within these containers. To assign a group policy, first

use the Group Policy snap-in for the Microsoft Management Console (MMC) to create a Group Policy object (GPO) and configure its settings, and then assign the GPO to the appropriate container. An object may have several GPOs influencing it (for example, one GPO assigned to the OU containing the object and another to the domain containing the OU). If this is the case, a conflict may occur, and then the last setting applied wins. Group policies are applied to users when they log on and to computers when they boot up. Users are subject to both GPO settings that apply to them as users and to GPO settings that apply to the computer at which they are working.

Group Policy. Using the Group Policy console to configure a Group Policy Object (GPO).

GPOs are really abstractions whose contents are stored in two different locations:

- **Group Policy Container (GPC):** This is a container within the Active Directory database on domain controllers that contains information about the globally unique identifier (GUID), version number, permissions, and inheritance of the GPO.
- **Group Policy Template (GPT):** This is a folder within the SYSVOL volume on domain controllers. It contains the actual GPO settings themselves and is identified by the GUID of the GPO.

Every Windows 2000 or Windows .NET Server domain has a default GPO that applies to all users and computers in the domain. Computers that are moved to a different domain lose the GPO of their original domain and

have the GPO of their new domain applied to them. The default GPO for a domain is the only GPO on which you can configure password restrictions, lockout restrictions, Kerberos, the Encrypting File System (EFS), and Internet Protocol (IP) security settings.

Notes

You cannot use Group Policy for Windows 2000 or Windows .NET Server to configure group policies for downlevel Windows NT, Windows 95, or Windows 98 clients. Instead, use System Policy Editor, a Windows NT tool that stores policy settings in a file called `ntconfig.pol` that modifies a portion of the Windows NT registry.

FullArmor offers a tool called FAZAM 2000 that simplifies the planning, deployment, and management of group policies. You can find more info at www.fullarmor.com.

Guest account

A built-in account in Microsoft Windows 2000, Windows XP, and Windows .NET Server used for guest access to network resources.

Overview

The Guest account is intended for occasional users who need temporary access to resources on the network. It is

disabled by default and can be enabled using User Manager for Domains. The Guest user account is a member of the Domain Guests global group and is assigned a null password during installation.

The Guest account is a domain user account on a domain controller. On a member server or workstation, however, there's a separate Guest local user account.

You should not enable the Guest account unless you are sure you will need it. You should also make sure that all your shared resources have correct permissions assigned to them because enabling the Guest account otherwise could pose a security risk.

See Also: Guests group

Guests group

A built-in group in the Microsoft Windows 2000, Windows XP, and Windows .NET Server operating systems whose members can be assigned guest access to network access.

Overview

The Guests group is a domain local group whose initial membership is the built-in Guest domain user account. If a member server or workstation joins a domain, the global group called Domain Guests is added to the local Guests group.

The Guests group has no preassigned rights or permissions. You can assign any network resource permissions to this group in order to grant temporary or guest users the access they require. Members of the Guests group do not have the right to make permanent changes to their desktop settings.

H.323

A videoconferencing standard developed by the International Telecommunication Union (ITU).

Overview

H.323 is a comprehensive suite of protocols for voice, video, and data communications between computers, terminals, network devices, and network services. H.323 is designed to enable users to make point-to-point multimedia phone calls over connectionless packet-switching networks such as private Internet Protocol (IP) internetworks and the Internet. H.323 was designed to replace the earlier H.320 standard that ran over circuit-switched services such as Integrated Services Digital Network (ISDN) telephone systems.

H.323 is widely supported by manufacturers of videoconferencing equipment, Voice over IP (VoIP) equipment, and Internet telephony software and devices. Any hardware or software system that supports the H.323 standard can communicate easily with any other H.323 system. With ordinary telephone communications, you can purchase a telephone from any vendor, plug it into your phone system, and the equipment works and inter-operates with other devices already on the system. The idea behind H.323 is to make multimedia communications over the Internet easy to set up and use.

Architecture

The H.323 protocol stack performs various functions related to establishing and maintaining real-time communications over voice, video, and data. H.323 does not represent a single standard, but rather an umbrella of many other ITU standards. The H.323 protocol stack includes more than two dozen G-level, H-level, and T-level protocols, including

- H.323 Conference Manager, which manages the establishment of multimedia conferencing connections
- The H.245 protocol, which controls communication with data terminal equipment (DTE)
- The H.225 protocol, which performs synchronization and framing mechanisms for multimedia data streams
- The T.120 protocol, which provides support for real-time, multipoint data communication

H.323 also specifies standard codecs for audio (G.723) and for video (H.263) that enable H.323 products to send and receive voice and video images. Specifically, H.323 defines standards for data codecs for audio transmission rates of 14.4 kilobits per second (Kbps) or faster, and video transmission rates of 28.8 Kbps or faster. H.323 recognizes the T.120 protocol for data conferencing and provides a set of standards-based conferencing features for audio and video conferencing.

Implementation

An H.323 network consists of four different types of entities:

- **Terminals:** These are the client end points for multimedia communications. An example would be an H.323-enabled Internet phone or PC.
- **Gateways:** These provide connectivity between H.323 networks and other communications services such as the circuit-switched Public Switched Telephone Network (PSTN).
- **Gatekeepers:** These provide services for call set up and tear down, and registering H.323 terminals for communications.
- **Multipoint control units (MCUs):** These support three-way and higher multipoint communications between terminals.

Marketplace

Many vendors provide H.323 videoconferencing systems and appliances. Examples include Polycom's

ViewStation MP, a popular system in many enterprise environments. Other vendors include Sony Corporation with its Contact system (which also works over ISDN) and VCON's MC6000 that is multicast-capable.

H.323. Components of an H.323 network.

PC-based H.323 collaboration software products include PictureTel Corporation's 900 Series appliances, which support both H.323 and H.320 communications; VCOM's MC8000; Intel Corporation's TeamStation; and VTEL Corporation's SmartStation.

Prospects

H.323 was extolled by industry in the 1990s but is now beginning to be considered legacy technology, suitable mainly for migrating legacy telephony systems to VoIP and for interoperating with legacy Private Branch Exchanges (PBXs). The problem is that H.323 was

designed with videoconferencing strictly in mind and is not flexible enough to support a full range of VoIP features.

A newer protocol proposed by the Internet Engineering Task Force (IETF) is Session Initiation Protocol (SIP), which is seen in some quarters as preferable for newer VoIP deployments. SIP is designed from the ground up to support IP and is slimmer and more flexible than H.323, a protocol known to have excessive overhead.

Notes

The OpenH323 Project is an initiative of Equivalence Pty Ltd. to develop an open-source version of the H.323 protocol suite licensed under Mozilla Public License (MPL).

H.323 gateway

A service that allows you to connect an H.323-based communication system on the Internet to a telephony system.

H.323 gateway. Making a phone call using an H.323 gateway.

Overview

You can use H.323 gateways to connect corporate networks to telephony systems for supporting integrated audio and video conferencing. For example, you can use an H.323 gateway to place a Microsoft NetMeeting call to someone's telephone. The Uniform Resource Locator (URL) format for doing so is "callto:<address>", in which <address> is the fully qualified domain name (FQDN), Internet Protocol (IP) address, or e-mail address of the person you are calling. You can use this URL as a link on a Web page or enter it directly in the address box of your Web browser.

NetMeeting does not include any H.323 gateway software, but third-party gateways are supported.

hacking

The action of trying to compromise the security of a computer system or network.

Overview

In the 1980s the term *hacker* was used to describe curious programmers who enjoyed getting into the nuts and bolts of how computer systems worked, usually UNIX systems and Transmission Control Protocol/Internet Protocol (TCP/IP) networks. In the 1990s hacking emerged as a malicious pursuit with the goal of stealing information, crashing systems, bringing down networks, and interfering with the daily activities of businesses and governments worldwide.

Various kinds of activities constitute hacking, but their overall similarity is that they are performed with malicious intent and without the knowledge or permission of the systems being hacked. Some of the different types of activities that hackers perform include

- **Footprinting:** The initial stage of a hacker's activities involves getting as much background information about the target system or network as possible. For example, a list of Internet Protocol (IP) addresses could be obtained through a simple whois query or by zone transfers from Domain Name System (DNS) servers.
- **Scanning:** Uses such tools as ping, traceroute, and netstat to identify the topology of a network and the types of hosts it contains. Port scanning involves testing hosts for open ports through which the attacker can gain access. Some common ports to scan include port 23 (telnet), 512 (rexec), and 513 (rlogin).
- **Enumeration:** The process by which hackers determine valid user accounts, names of shared resources, versions of installed applications, and other information.
- **Sniffing:** Using widely available tools, hackers can quietly capture traffic between clients and servers in order to obtain credentials and other useful information for breaking into systems.
- **Diffing:** This involves comparing two files for differences, and it is typically used to try to extract encrypted passwords from database files in which they are stored. Once extracted, these encrypted passwords can be subjected to dictionary and brute force attacks to try to crack them.
- **Back doors:** Software manufacturers sometimes leave secret user accounts created in their products so administrators have a "back door" to get in if they lock themselves out by invalidating their account. Hackers test commercial software to try to find such back doors. Also, once hackers have compromised a system, they generally try to create a back door for themselves on the system in case they are discovered and locked out.
- **Wardialing:** Using automated dialing software and modems to try to find entry points to remote networks.
- **Script Kiddies:** Novice hackers who employ scripts and other tools written by experienced hackers to test systems for vulnerabilities and launch automated attacks.
- **Social engineering:** A potentially devastating form of attack in which the hacker enters the building posing as a system administrator, repair person, or other trusted individual and gains unauthorized access to network resources. This takes more guts than the usual forms of hacking, though!

Types

Hacker attacks fall under a number of different categories, including the following:

- **Denial of Service (DoS):** Blocks access by legitimate users to a system or network by using up all available resources. Examples include LAND attacks, SYN flooding, Smurf attacks, and Teardrop attacks. The first famous DoS attack was the Internet Worm created by Robert Morris in 1988. Another notable attack was developed by Kevin Mitnick in 1995 to exploit weaknesses in the Internet Control Message Protocol (ICMP) and Transmission Control Protocol (TCP) protocols that had long been recognized in academic circles but had never been deliberately exploited.
- **Distributed Denial of Service (DDoS):** Employs large numbers of compromised intermediate machines called zombies to launch an overwhelming attack against a system or network. In February 2000, DDoS attacks were launched against a number of high-profile Web sites, including Yahoo!, and brought down these sites for several hours.
- **Elevation of privileges:** The goal is to enable the attacker to elevate his privilege level for accessing system resources from anonymous user to root (administrator), if possible.
- **Buffer overflow:** Flaws in software may cause systems to crash when invalid data is submitted through Uniform Resource Locators (URLs), Web forms, and other user interfaces. Besides crashing systems, buffer overflows can sometimes give hackers the ability to execute arbitrary code on the systems affected.
- **Spoofing:** Assuming the identity of a trusted user or of another system in order to gain access to a resource.
- **Session hijacking:** This involves taking the place of the client in an existing client/server connection such as a TCP connection. Session hijacking is a form of the man-in-the-middle attack.

Notes

The Openhack Project was developed by eWeek Labs to help publicize the issues around hacking of business

networks. The project challenged people to try deliberately attacking a test bed network, and the results of these attempts were published to help educate people on how hackers perform their attacks.

Hailstorm

An emerging platform for development of Internet-based services from Microsoft Corporation based on its new .NET platform.

Overview

In many ways, Microsoft Hailstorm represents the next evolutionary stage of the Internet. Hailstorm is a user-centric architecture based on Microsoft's .NET platform and on the open standards Extensible Markup Language (XML), Simple Object Access Protocol (SOAP), and Universal Description and Discovery Interface (UDDI).

Hailstorm provides users with a standard set of Web services that enables users to collaborate and participate in business transactions seamlessly and transparently. Hailstorm places control squarely in the user's court—data is not shared unless users explicitly grant their consent to do so. This makes Hailstorm a secure platform for 21st-century business communications in the Internet economy.

Initial support for Hailstorm is included in Microsoft's Windows XP, Office XP, and Xbox platforms. Hailstorm transforms MSN Messenger into an enterprise and consumer development platform for building advanced user experiences that leverage the power of Internet-based instant messaging.

Architecture

Hailstorm services are designed to allow users to access their data from a variety of platforms, including traditional PCs, Tablet PCs, handheld Personal Digital Assistants (PDAs), mobile phones, and other Web appliances. User data is stored in a distributed fashion and can be securely accessed from any device and any location with the user's consent.

Users and applications access Hailstorm services through end points, which may be applications, devices, or services. With a user's consent, Hailstorm automatically connects end points to widely distributed Web services to perform transactions desired by the user. Hailstorm services are XML-enabled Web services running on the .NET platform and are built upon the foundation service Microsoft Passport, which provides security and authentication to perform transactions. Other parts of a user's experience supported by Hailstorm's Web services include profile information, location information, and calendar information. The table lists the initial set of core Web services to be included in Hailstorm.

Initial Set of Web Services Included in Microsoft Hailstorm

<i>Service</i>	<i>Description</i>
myAddress	User's address
myApplication Settings	User's application settings
myCalendar	User's time and task management information
myContacts	User's list of contacts
myDevices	Settings and capabilities of user's devices
myDocuments	Location for storing user's personal files
myFavorite WebSites	User's favorite Uniform Resource Locators (URLs)
myInbox	User's inbox for e-mail and voice mail
myLocation	User's geographical location
myNotifications	User's subscriptions and notifications
myProfile	User's personal profile information such as nickname, birth date, etc.
myServices	Services provided to user by Hailstorm
myUsage	User's usage of Hailstorm services
MyWallet	Receipts, coupons, and payment instruments for user's transactions

HAL

Stands for hardware abstraction layer, a thin layer of software at the base of the Microsoft Windows 2000, Windows XP, and Windows .NET Server operating systems that provides portability between different machine architectures and processor platforms.

See: hardware abstraction layer (HAL)

half-duplex

A mode of communication where at any given moment data can be either transmitted or received but cannot be transmitted and received simultaneously.

Overview

The simplest example of half-duplex communications is using a walkie-talkie: you have to press a button to talk and release the button to listen. When two people use walkie-talkies to communicate, at any given moment only one of them can talk while the other listens. If both try to talk simultaneously, a collision occurs and neither hears what the other says.

Communication through traditional hub-based Ethernet networks is another example of half-duplex communications. When one station on an Ethernet network transmits, the other stations detect the carrier signal and listen instead of transmitting themselves. If two stations transmit signals simultaneously, a collision occurs and both stations stop transmitting and wait random intervals of time before retransmitting.

By contrast, full-duplex communication enables stations to transmit and receive signals simultaneously, with the advantage of providing twice the bandwidth of equivalent half-duplex technologies. However, full-duplex requires two communication channels to achieve these results—one to transmit and one to receive signals. Hub-based Ethernet networks can only be used for half-duplex communications—for full-duplex Ethernet, you need switches instead of hubs.

A third mode of communications is called simplex, which involves transmission in one direction only, with one station transmitting signals and the other receiving

them. A television broadcast is a simple example of simplex communications.

Stands for home area network, a network of several computers at a user's home.

handheld

Generally used to refer to Personal Digital Assistants (PDAs) and other computers that can be held in the palm of the hand.

Overview

In the late 1990s the handheld market became popular among consumers for managing contacts, appointments, and other personal information. At the end of the decade, the issue arose as to which of the two common platforms, Palm and Microsoft Windows CE, would dominate in the enterprise market. The outcome is still uncertain. Palm has the advantage of a large installed base, a wide range of third-party applications, and support by such popular wireless services as AvantGo. The new PocketPC platform has made the Windows CE operating system competitive with the PalmOS by providing interoperability with Windows-based services, and pocket versions of Microsoft Office applications, Microsoft Internet Explorer. At the end of 2000, analysts reported that Palm held three-quarters of the handheld market share and Windows CE held only 18 percent, but the Windows CE has been gaining market share steadily.

A newcomer to the handheld market is the Linux PDA, represented by Agenda Computing's VR3. It is too soon to say what impact porting Linux to the handheld platform will have on market leaders Palm and PocketPC.

Handheld Device Markup Language (HDML)

A markup language loosely modeled on Hypertext Markup Language (HTML) and optimized for providing Internet access to cell phones and other handheld devices.

Overview

Handheld Device Markup Language (HDML) was developed by Unwired Planet (now Phone.com) to enable mobile communications devices such as cell phones and Personal Digital Assistants (PDAs) to access content on the Internet. Such devices usually have limited size displays (typically four lines by 20 characters or smaller) and limited processing power that make them require that information they download from the Internet be specially formatted to meet these requirements.

HDML is not intended as a means of delivering standard HTML-formatted Web content to such devices—most standard Web pages simply cannot be reformatted to fit on devices with such small display areas. HDML is not a subset or scaled-down version of HTML but an entirely new markup language specifically designed from the ground up for these devices.

HDML can be used to deliver a broad range of time-sensitive information to handheld wireless devices, including appointments, weather information, stock quotes, telephone directory white pages, inventory, catalog pricing, and similar business and commercial information. Scripts can be developed to extract this kind of information from the databases in which it resides and format it into HDML cards in much the same way that Perl can be used to write scripts to access database information stored on UNIX servers or that Active Server Pages (ASP) can be used to build Web-based applications that connect to Structured Query Language (SQL) databases.

HDML is an open standard guided and licensed by Phone.com. The current version of this technology is HDML 2.

Implementation

HDML provides a way to format information for delivery to handheld wireless devices that support packet-switched Internet Protocol (IP) services instead of traditional circuit-switched cellular services. HDML uses the same Hypertext Transfer Protocol (HTTP) as its application layer protocol, just as HTML does. The difference is that an HDML/HTTP system uses three components (client, server, and gateway) instead of the traditional two (client and server) used by HTML/HTTP.

Handheld Device Markup Language (HDML). How an HDML communications system works.

When a user with an HDML-enabled client device (a device running an HDML browser) wants to access HDML-formatted content on a Web server, the client device communicates over the provider's cellular network with a special gateway server called an UP.Link Gateway. This gateway server then "gates" the user's request over a Transmission Control Protocol/Internet Protocol (TCP/IP) wireline connection to the Web server. The Web server responds with the requested content that is then "gated" back to the client over the cellular network.

HDML uses a navigation model that is based on a filing card metaphor. Cards of HDML-formatted information are grouped into "activities," which facilitates the development of HDML-based applications. The user can enter information and share it among cards using variables, and the user can parameterize cards so that a family of cards differing only in the value of a variable can be stored more efficiently in the limited-size cache of these devices. You can use variables to create forms for entering information in HDML applications. HDML currently does not support scripting, branching, or conditional statements.

Marketplace

HDML is currently used by more than 80 cellular and mobile carriers in the United States, including AT&T, Ameritech, and Bell Atlantic. Some analysts estimate that more than 90 percent of Internet-enabled phones sold in the United States support HDML and include Phone.com's HDML browser. Outside the United

States, the competing Wireless Markup Language/ Wireless Application Protocol (WML/WAP) combination is more popular (WAP shares many of the features of HDML and was developed from HDML).

Prospects

WAP is currently gaining popularity at the expense of HDML and may eventually replace it. One indication of this is Nokia and Ericsson, which are two major players in the world cellular market and which provide WAP-enabled phones. Nokia is even giving away the source code for its WAP browser to promote this standard. Meanwhile, enterprises that want to deploy mobile clients with Internet access have to support two interoperable solutions, HDML and WAP.

handshaking

The process that establishes communication between two telecommunications devices.

Overview

When two computers first connect with each other through modems, the handshaking process determines which protocols, speeds, compression, and error-correction schemes will be used during the communication session. Handshaking is necessary at the start of each session because typically the modems differ in their vendor, model, or hardware/software configuration. The handshake ensures that communication is possible despite these differences.

The term *handshaking* arises from the analogy of two people meeting to conduct business. They first shake hands to greet each other, announcing their names, titles, and intentions. They might also "size each other up" to determine the other person's capacities and capabilities.

During the handshaking process, both modems send the other a series of control signals and respond to each other's signals. Handshaking is also referred to as "flow

control” because the process establishes the ground rules for managing the flow of data between the two devices. Some of the parameters that the modems need to negotiate are

- The maximum transmission speed, taking into consideration the speed of both modems and the quality of the transmission
- The length of the line delay to apply echo cancellation
- The communication protocol

Modern modems transmit the control signals in full-duplex mode over the RS-232 interface that connects them to the computers.

hardware abstraction layer (HAL)

A thin layer of software at the base of the Microsoft Windows 2000, Windows XP, and Windows .NET Server operating systems that provides portability between different machine architectures and processor platforms.

Overview

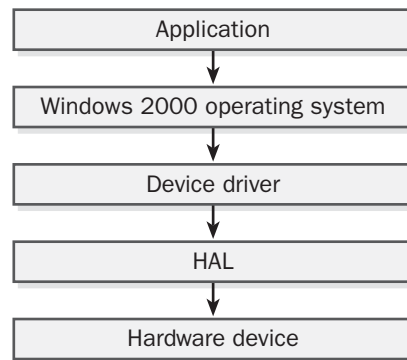

The hardware abstraction layer (HAL) hides hardware differences from the operating system so that uniform code can be used for all hardware. The HAL thus offers a uniform interface between the underlying hardware and the higher layers of the operating system. All underlying hardware looks the same to the Windows 2000, Windows XP, and Windows .NET Server operating systems because they “see” the hardware through the filtered glasses of the HAL.

The HAL is located at the base of the Executive Services, and it encapsulates most hardware-specific functions that are performed by the operating system. If another portion of the operating system wants to access a hardware device, it must refer its request to the HAL. The HAL handles all communication between the kernel of the operating system and the hardware,

particularly those regarding processor commands, system interrupts, and input/output (I/O) interfaces.

Implementation

The HAL is implemented in Windows 2000, Windows XP, and Windows .NET Server as a loadable kernel mode module called hal.dll that is located in the System32 directory. If a hardware vendor needs to protect proprietary technology, the company can develop a custom implementation of the HAL. This means, for example, that different processor configurations such as multiprocessor machines might use different HAL drivers.

Hardware Abstraction Layer (HAL). How a Windows 2000 application communicates with hardware through the HAL.

Usually, what happens when Windows 2000, Windows XP, or Windows .NET Server want to access a hardware device is that the operating system issues a command to the appropriate device driver, which then talks to the HAL, which talks directly to the hardware.

Using the wrong HAL driver can result in degraded system performance since all hardware calls made by the operating system go through the HAL. Contact your vendor to make sure that you have the correct HAL for your system. To check which HAL is installed on your system, open the Setup.log file found in the \Winnt\Repair directory and examine the filename after the equal sign. The following table shows a list of HALs that can be installed from the Windows 2000, Windows XP, and Windows .NET Server compact disc.

HALs Found on the Windows 2000, Windows XP, and Windows .NET Server Compact Disc

<i>File name</i>	<i>Description</i>
hal.dll	Used for standard PCs
halacpi.dll	Used for PCs supporting Advanced Configuration and Power Interface (ACPI)
halapic.dll	Used for PCs supporting Advanced Programmable Interrupt Controller (APIC)

hardware address

Also called a MAC address, a unique 6-byte (48-bit) address that is usually permanently burned into a network interface card (NIC) or other physical-layer networking device and uniquely identifies the device on an Ethernet-based network.

See: MAC address

Hardware Compatibility List (HCL)

A list of hardware that is compatible with a Microsoft Windows operating system product.

Overview

The Hardware Compatibility List (HCL) for a Microsoft Windows platform defines all supported hardware, including computer systems as well as individual hardware components such as video cards, motherboards, and sound cards. When in doubt, you should consult the HCL before installing an operating system

on a nonstandard or customized machine or installing new hardware into a system with an existing operating system. Using components not included on the HCL can lead to installation failures or system instabilities. Microsoft has determined that drivers for hardware devices listed on the HCL are compatible with that version of Windows; Microsoft supports only these drivers.

If you use drivers for devices that are not on the HCL, you might not be entitled to Microsoft product support for your system configuration. If you must use non-HCL devices, contact the device's manufacturer to see whether a supported driver exists for the particular Windows operating system you are using. If you contact Microsoft Product Support Services (PSS) about a problem and the support engineer determines that a hardware device in your system is not on the HCL, you will likely incur a charge for the call even if the problem cannot be resolved.

Notes

You can usually find the HCL for a particular Windows operating system on its distribution CD. (The file might be called hcl.txt.) A more up-to-date version of the HCL for all Windows operating system platforms is available on the Web at the HCL site listed in the "For More Information" section of this entry.

For More Information

You can visit Microsoft Product Support Services at www.microsoft.com/support. You can look at the Microsoft HCL site at www.microsoft.com/hwtest/hcl.

hardware profile

Information about the configuration of devices and services that are used to boot an operating system into a certain configuration.

Overview

A hardware profile tells the operating system which devices are present when the computer boots.

You can create several different hardware profiles on Microsoft Windows operating systems and select the one you want to use at boot time. For example, if

Windows 2000 is installed on a laptop computer, you can create two hardware profiles for that computer:

- One profile for when the computer is docked and connected to the network. (The profile will contain configuration information for the network adapter.)
- Another profile for when the computer is undocked and used in the field. (The profile will contain no configuration information about networking.)

When the laptop is booted, you select the appropriate hardware profile from a menu generated by the operating system.

Notes

Hardware profiles are usually not necessary for plug-and-play laptops running Windows 2000, Windows XP, or Windows .NET Server. These computers can recognize when new hardware becomes available (for example, by docking) and automatically configure themselves.

hashing algorithm

A mathematical procedure for randomizing (hashing) information to make it more secure in transmission.

Overview

Hasting algorithms take information and scramble it repeatedly to create a fixed-length string of numbers and characters called a hash. A good hashing algorithm has the following characteristic: if you apply a hashing algorithm to some data and then change only a few bits in the data and apply the algorithm again, the two resulting hashes will differ in almost every bit.

Hashing algorithms are used extensively in cryptography for encrypting keys or messages. Examples of popular cryptographic hashing algorithms include MD2, MD4, MD5, and SHA-1. Message Digest 5 (MD5) uses a 128-bit hash, and Secure Hash Algorithm (SHA) uses a 60-bit hash. The more bits in a hash, the greater the security of the encryption process.

Hashing is also used in some database technology for creating indexes of items in a database. Hashes of database objects are generally smaller than the objects themselves, so they can be indexed and searched more quickly. You can generate unique hashes of fixed length

for each database record, creating a hash table that you can use for quick searches for records.

H channel

A designation for groups of channels on Basic Rate Interface ISDN (BRI-ISDN) services.

Overview

H channel standards are defined by the International Telecommunication Union (ITU) and are composed of different combinations of Integrated Services Digital Network (ISDN) B channels. The most common configurations are as follows:

- **H0 channel:** This consists of six B channels multiplexed to provide a data transmission speed of 384 kilobits per second (Kbps). This service is sometimes called ISDN H0 or switched 384.
- **H11 channel:** This consists of 24 B channels to provide 1536 kilobits per second (Kbps) of bandwidth. This is sometimes called ISDN H11 or switched 1536.
- **H12 channel:** This consists of 30 B channels to provide 1920 Kbps of bandwidth. This is sometimes called ISDN H12 or switched 1920.

HDSL

Stands for High-bit-rate Digital Subscriber Line, a form of Digital Subscriber Line (DSL) technology that provides T-1 speeds in both directions.

See: High-bit-rate Digital Subscriber Line (HDSL)

header

The initial portion of a packet or a frame.

Overview

The header typically contains control information such as addressing, routing, and protocol version. The format of this information depends on the protocol being used. For example, an Internet Protocol (IP) header contains information about the version of the IP protocol, the length of the header, the type of service used, the packet's Time to Live (TTL), the source and destination address, and other data. Headers are used to control the flow of packets through the network or over the communication link.

The end of a frame sometimes has a smaller structure called a footer or trailer, but this usually contains only error-checking information. Control information is always placed in the header because this is the first portion of the packet or frame that is read by a networking device such as a switch or a router.

heartbeat

A polling feature of cluster servers.

Overview

An internal communications interface in Microsoft Cluster Server (MSCS) in Microsoft Windows NT Server, Enterprise Edition, and in the Cluster service in Windows 2000 Advanced Server and Windows .NET Enterprise Server, the heartbeat continuously provides interserver communication between cluster nodes in a cluster. One function of the heartbeat is to generate a message that the Cluster service running on one node regularly sends to the Cluster service on the other node to detect a failure within the cluster. Nodes in a cluster communicate status information with each other through the heartbeat using MSCS or the Cluster service. These messages appear as network traffic between the two nodes in the cluster on the dedicated network connection between the nodes, which is called the private network of the cluster. The primary heartbeat network interface is usually a crossover network cable directly attached between cluster nodes or in a private network. If the heartbeat is lost over the private connection, Cluster Server reverts to a public network or alternate connection for its heartbeat and other Cluster service traffic. You can configure the polling interval for the heartbeat using Cluster Administrator.

Help

Any of several systems of online help for Microsoft Corporation products.

Overview

The type of help features available depends on the nature of the product, the date of release, and the context in which it is invoked. Examples of help functions include the following:

- **Help:** Choose Help from the Start menu in Microsoft Windows 95, Windows 98, Windows NT, Windows 2000, Windows XP, and Windows .NET Server to open a Help Topics window (in Windows XP and Windows .NET Server, the window is called "Help And Support Center"). The window has three tabs: Contents (to browse the help database using a

hierarchical set of book icons), Index (to type the topic you want help on and then display the appropriate entry), and Find (named Search in Windows 98 and Windows 2000, to conduct a full-text keyword search of the help database). Windows 2000 includes a fourth tab, Favorites, that lets you save links to Help topics.

In Windows XP and Windows .NET Server, Help has an entirely new look and setup. It now resembles Internet Explorer and offers many new features and customized user options. For example, the mechanism to search Microsoft Online has been integrated into the main search engine.

- **What's This?:** To find information about a setting in a dialog box or property sheet, right-click the item and choose What's This? from the context menu, or click the question mark button at the top right of the dialog box.
- **F1 key:** To get context-sensitive help at any point, press the F1 function key.
- **Browser-based help:** In Windows 2000, online help is provided through a new interface called Online Support and Information, which is accessible in Windows 2000 Help by selecting Web Help. The interface displays a new page within Windows 2000 Help that provides links to various Windows 2000 online support Web pages, including a new Windows 2000 Resource Kits Web page.
- **Books Online:** Many Microsoft products have additional user manuals in an online format that you can access from the Start menu.

heterogeneous network

A network that uses multiple network architectures and operating systems.

Overview

An example of a heterogeneous network at the hardware level is a combination of Ethernet and Token Ring local area networks (LANs) connected with a Fiber Distributed Data Interface (FDDI) backbone. An example at the network operating system (NOS) level is a server room in which some machines are running Microsoft Windows NT, others are running UNIX, and still others

are running Novell NetWare. An example at the application level is a messaging system that includes Microsoft Exchange Server, Novell GroupWise, UNIX Sendmail, and IBM PROFS mail systems.

Heterogeneous networks are generally more complex to administer than homogeneous networks. Most networks are heterogeneous because they evolve over time. Most startup companies cannot afford to buy a completely homogeneous, state-of-the-art network platform, and even if they could, it would soon become out of date. One advantage of deliberately maintaining a heterogeneous network is that customers can use any product they choose instead of being locked into a single vendor's system. Networking and operating system choices can be made on a "best-served" basis instead of an "only buy from us" approach.

See Also: *homogeneous network*

hidden share

A share not visible when users browse the network for resources.

Overview

In Microsoft Windows operating systems, a share with a dollar sign (\$) appended to the share name. Hidden shares are accessible on the network using Universal Naming Convention (UNC) paths or mapped network drives, but only if the user knows that they are present and knows their exact name. These shares do not show up in My Network Places or Windows Explorer or when you use the net view command. Users are unaware of their presence unless they are specifically informed.

It is a good idea not to acquaint ordinary users with hidden shares, because they might create such shares on their workstations if appropriate file and print services are installed. This can lead to secret, uncontrolled publishing of information within the company, which is usually against company policy.

Windows 2000, Windows XP, and Windows .NET Server also create certain hidden shares during the installation process that the operating system uses for specific purposes. These hidden shares are called administrative shares; permissions on them should not be modified.

Hierarchical Storage Management (HSM)

A data storage system for archiving infrequently needed data while still making it easily available.

Overview

A Hierarchical Storage Management (HSM) system is a way of providing users with seemingly endless amounts of storage space. This is accomplished by moving much of the data from hard disks to an archival storage system, such as an optical drive or tape library. Pointers are created on the hard disks indicating where the archived data is located. Users who need access to data need only request it from the disk, and if the requested data has been archived, the pointers allow the data to be found and returned to the user. The whole process is transparent from the user's viewpoint—all the data appears to be stored on the hard disks.

Hierarchical Storage Management (HSM). How an HSM system works.

Implementation

HSM defines two types of storage:

- **Online storage:** This is storage immediately accessible to users, typically hard disks on servers. Online storage is relatively expensive and provides almost instantaneous seek/return of requested data.

In Microsoft terminology this form of storage is called local storage.

- **Nearline storage:** This is storage on archival media such as tape or optical disk and employs automated seek/return technologies such as robotic tape libraries. Nearline storage is cheaper than online storage but is slower in its ability to return requested data. In Microsoft parlance, this type of storage is known as remote storage.

Note that nearline storage differs from offline storage, which uses removable archive media (usually tape) that needs to be manually inserted in order to access information stored on the media. For HSM to work, the archival storage system employed must be automated or nearline in operation.

In HSM, when an online storage system approaches full capacity, HSM automatically starts to archive files, directories, or whole volumes to nearline storage. The particular data archived depends on the policies configured for HSM's operation, which typically initiate file archiving based on how frequently files have been accessed or when they have last been accessed. The archiving process happens automatically, and files moved from online storage are replaced with pointers to their nearline location. When a user tries to access a file stored nearline, the file is moved to online storage where the user can read it (the user cannot read nearline storage directly).

Marketplace

HSM systems have been around for some time in the UNIX world as third-party add-ons developed by different vendors for enterprise environments. Microsoft now includes an integrated HSM system in its Microsoft Windows 2000 Server platform called Remote Storage Service (RSS), which can archive data to Small Computer System Interface (SCSI) tape libraries using 4mm, 8mm, and digital linear tape (DLT) tape formats (quarter-inch cartridge [QIC] tapes and optical disk libraries are not supported). RSS works by using a new feature of NTFS version 5 called reparse points, which are similar to pointers used by UNIX file systems.

Issues

Traditional HSM loses its usefulness when used to archive large files such as video feeds and database files. This is because users sometimes need to access only a portion of such a file, but in order for them to access it, the entire file must be fetched from nearline storage and moved to online storage, a process that can take excessive time (for example, retrieving a 2 gigabyte (GB) file from a DLT tape library could take five minutes or more). A recent solution to this problem is the implementation of file segmentation to HSM systems. Using file segmentation, large files are broken up into smaller segments for archiving and retrieval, and when a part of a file is modified, only the segment modified needs to be rearchived. File segmentation can be implemented on UNIX-based HSM systems by employing a segmentation attribute—setting this attribute causes a file, directory, or volume to be broken into segments when moved to nearline storage, with pointers to each segment created on the online storage where the object previously resided. The whole process is again transparent to the user and typically reduces seek/return time for portions of large files to seconds instead of minutes.

Notes

Note that HSM systems such as Microsoft's RSS are not a substitute for regular tape backups. HSM will not archive critical operating system and application files, so regular backups are still necessary when using such systems.

High-bit-rate Digital Subscriber Line (HDSL)

A form of Digital Subscriber Line (DSL) technology that supports high-speed symmetric data transmission.

Overview

High-bit-rate Digital Subscriber Line (HDSL) can be used to transmit data over existing copper local loop connections at T1 or E1 speeds. It is used to transport data only (HDSL signals overlap the voice portion of the Plain Old Telephone Service [POTS] spectrum and therefore cannot carry voice) and is generally used in wide area networking (WAN) scenarios. The maximum distance for HDSL transmission is typically 15,000 feet (4500 meters) when running over unconditioned copper

twisted-pair telephone wiring. Some providers, however, claim that their devices support twice this distance. This maximum distance from the telco's central office (CO) to an HDSL customer's premises is sometimes called the Carrier Service Area (CSA).

HDSL was the earliest symmetric version of DSL to be widely implemented and was designed in the early 1990s as an alternative to traditional T-1 services. T1 lines originally required intermediate repeaters to be installed every 6000 feet (1830 meters) between termination points in order to ensure the signal strength necessary to transport data at such high speeds. HDSL was developed by Bellcore as a repeaterless form of T1 that would save the cost of installing repeaters and speed deployment of T1 lines for customers.

HDSL comes in various formats, including the following:

- 668-kilobit-per-second (Kbps) full-duplex transmission over a single unconditioned, unshielded copper twisted-pair phone line. This is an early form that is not used much anymore.
- 1.544-megabit-per-second (Mbps) full-duplex transmission (T1 speed) over unconditioned, unshielded copper twisted-pair cables. This is the most common configuration and is called Dual-Duplex HDSL. It uses twisted-pair phone lines with two pairs of wires (four wires) within the line, with full-duplex 784-Kbps transmission taking place over each pair of wires.
- 2.048-Mbps full-duplex transmission (E1 speed) over two or three unconditioned copper twisted-pair lines. This is the European form of HDSL, and two pairs is the usual form nowadays.

Implementation

The main difference between HDSL and the original T1 specification is the line coding scheme employed. T1 lines originally used bipolar alternate mark inversion (AMI) for signal encoding, which has a spectral efficiency of only 1 bit/ baud (in other words, to transmit one bit of data requires one symbol or character). By contrast, HDSL employs 2B1Q (2 Binary 1 Quaternary) line coding, which transmits information at 2 bits/ baud (2B1Q is also the encoding scheme for Integrated Services Digital Network [ISDN]). Each pair of copper phone wires in an

HDSL implementation carry data at 784 Kbps over unconditioned lines without the need of repeaters. Two pairs of copper wires thus provide a throughput of 1.536 Mbps, which is the same as regular T1.

In a typical scenario, a line driver called an HTU-R terminates the lines at the customer premises end through a serial connection to a router that provides connectivity for the customer's local area network (LAN). At the telco end, a similar line driver called an HTU-C terminates the other end and provides a connection to the digital cross connect (DCC) that routes signals to trunk lines between central offices (COs). A group of HTU-Cs are typically combined in a rack to service more customers.

High-bit-rate Digital Subscriber Line (HDSL). Some possible deployment scenarios for HDSL.

Uses

Because it is a high-speed symmetrical service, HDSL is typically used to provide dedicated WAN links for enterprises. Many telcos now offer HDSL instead of traditional T1 lines because of reduced deployment

costs associated with this repeaterless technology. An enterprise customer wanting to run a public Web server at her company site might use HDSL to provide a high-bandwidth connection between the server and the Internet.

HDSL can also be used for connecting bridges, routers, and telephone equipment such as Private Branch Exchanges (PBXs) over a campus using HDSL line drivers with built-in Channel Service Unit/Data Service Unit (CSU/DSU) functionality. It can also be used to build private data telecommunications networks, connections between points of presence (POPs), and other telecommunications services. You can use HDSL to connect campus networks and phone equipment at T1 speeds without the need for costly fiber-optic cabling. HDSL line drivers or line terminals generally support a variety of data interfaces, including V.35, G.703, and 10BaseT connections. They are configurable for Nx64 Kbps transmission speeds and sometimes include bridge or router functionality for framing of High-level Data Link Control (HDLC), Point-to-Point Protocol (PPP), Internet Protocol (IP), and other protocols. They can be used for LAN-LAN connections and for connecting LANs to frame relay networks or the Internet.

HDSL can also be used for other purposes such as videoconferencing, telecommuting, and shared Internet access for connecting business networks to the Internet. HDSL is not used for residential Internet access—Asymmetric Digital Subscriber Line (ADSL) is commonly used there instead. ADSL is able to provide line sharing (combined voice/data services over a single pair of copper lines), but HDSL carries only data and requires two pairs of lines.

Prospects

A newer form of HDSL called HDSL2 works similarly to HDSL but requires only one pair of copper lines in order to operate. HDSL2 is standardized by the International Telecommunication Union (ITU) as G.991.1 and by the American National Standards Institute (ANSI) as T1E1.4.

High-level Data Link Control (HDLC)

An encapsulation protocol for point-to-point wide area network (WAN) links.

Overview

High-level Data Link Control (HDLC) is a data-link layer protocol for synchronous communication over serial links. HDLC was developed in the 1970s by IBM as an offshoot of the Synchronous Data Link Control (SDLC) protocol for their Systems Network Architecture (SNA) mainframe computing environment. It was later standardized by the International Organization for Standardization (ISO) as a standard Open Systems Interconnection (OSI) Layer-2 protocol.

Architecture

HDLC is called an encapsulation protocol because it encapsulates bit stream data into fixed-length frames for transmission over synchronous serial lines. HDLC is a bit-stream protocol (bit streams are streams of data not broken into individual characters) that uses a 32-bit checksum for error correction and supports full-duplex communication. HDLC frames consist of a special flag byte (01111110) followed by address and control information, data bits, and a cyclic redundancy check (CRC) byte. A control field at the start of a frame is used for establishing and terminating data link connections. As a data-link protocol, HDLC is responsible for ensuring that data is received intact, without errors, and in the proper sequence. HDLC also supports flow-control mechanisms for managing synchronous data streams. HDLC also supports multiple protocols but does not include any mechanisms for authentication (since authentication is not really needed in dedicated point-to-point communications).

An HDLC link typically consists of a primary station and a secondary station, with the primary station issuing the commands and the secondary station issuing the responses. HDLC is used mainly for point-to-point communication, in contrast to other WAN transports such as Asynchronous Transfer Mode (ATM), frame relay, and X.25, which can be used for both point-to-point and point-to-multipoint communication. Because HDLC is used mainly in point-to-point communication, it does not need to have addressing implemented at the data-link

layer because the local and remote stations are connected directly. In this configuration, either one station is the primary and the other the secondary (unbalanced point-to-point link) or both stations function in a primary/secondary capacity (balanced point-to-point link). You can also use HDLC in a more complex configuration in which one primary links to several secondaries (unbalanced multipoint configuration), but this is not common.

High-level Data Link Control (HDLC). Using HDLC for WAN communications over a leased line.

Implementation

HDLC is the default encapsulation protocol employed by Cisco routers for synchronous transmission over serial links such as Integrated Services Digital Network (ISDN) and T-1 lines. For point-to-point communications over a leased line using Cisco routers at both ends, HDLC is a good choice. A typical leased-line configuration uses Channel Service Unit/Data Service Units (CSU/DSUs) to terminate the ends of the leased line, with Cisco routers connecting the CSU/DSUs to the two networks. The CSU/DSUs are nowadays often integrated into the routers for simplicity.

Issues

When HDLC was first developed, vendors made their own modifications to the protocol, with the result that versions of HDLC from different vendors cannot inter-

operate with each other. This was the driving force behind the development by the Internet Engineering Task Force (IETF) of Point-to-Point Protocol (PPP), a newer encapsulation protocol that has largely replaced HDLC in WAN environments. PPP supports both synchronous and asynchronous communications and has a standard implementation by every vendor to ensure interoperability between networking equipment from different vendors. Both PPP and Link Access Protocol, Balanced (LAPB), the data-link protocol for X.25, evolved from HDLC and were built upon its foundation.

Notes

A version of HDLC known as Normal Response Mode (NRM) HDLC is basically the same thing as Synchronous Data Link Control (SDLC), a protocol developed by IBM as a replacement for its BiSync protocol.

High Performance File System (HPFS)

A file system designed for version 1.2 of the Microsoft/IBM OS/2 operating system as a successor to the file allocation table (FAT) file system used by MS-DOS.

Overview

High-Performance File System (HPFS) improves on the performance of the FAT file system for MS-DOS in the following ways:

- It locates file directory and allocation information in close physical proximity to the files themselves on the hard disk. (The FAT file system locates the root directory and allocation information on the outermost cylinders of the drive.)
- It has a more robust and efficient file system tree structure than FAT, so you can locate directories more quickly.
- It has multiple asynchronous read/write threads.
- It uses sector-based allocation instead of the more space-wasting, cluster-based allocation used by FAT.

- It uses large file cache sizes and lazy-writes.

Other features of HPFS that were considered advanced at the time of its development included the following:

- Long filenames—up to 256 characters in length. These long filenames are case preserving but not case sensitive. MS-DOS applications can still access HPFS volumes either over the network to an OS/2 LAN Manager server or from inside an MS-DOS compatibility box on an OS/2 workstation.
- Extended attributes—a series of name/value pairs associated with each directory or file. These extended attributes can be 64 kilobytes (KB) in size and support advanced kinds of search queries, such as by file type, version number, subject, or comments.
- Support for extended character sets.
- Maximum 64-gigabyte (GB) drive size. (The practical limit is 16 GB, however.)

Notes

HPFS is supported by Microsoft Windows NT version 3.51 but not by the Windows NT 4, Windows 2000, Windows XP, or Windows .NET Server operating systems, which use the more advanced NTFS file system (NTFS). HPFS was designed to function as an Installable File System (IFS), which is implemented as a dynamic-link library (DLL) that hooks into the file system component of the operating system kernel. In Windows NT 3.51, you configured HPFS through an IFS= line in the config.sys file. The CD file system (CDFS) was also designed to support IFS.

High-Performance Parallel Interface (HIPPI)

A gigabit networking technology for point-to-point communications.

Overview

High-Performance Parallel Interface (HIPPI) is an American National Standards Institute (ANSI) standard for point-to-point networking at gigabit speeds. HIPPI was developed in the 1980s as a technology for

interconnecting supercomputers, mainframes, and their storage devices. Fibre Channel is the closest networking technology to HIPPI in terms of its use and capabilities and is more widely used than HIPPI.

Uses

While HIPPI is comparable in speed to Gigabit Ethernet (GbE), it is not widely used in general networking applications since it is basically a connection-oriented technology suitable for point-to-point communications due to latency involved in negotiating connections.

HIPPI also lacks the multicasting capability provided by Internet Protocol (IP)-based GbE. HIPPI is mostly deployed in a few high-speed research projects by universities and for high-speed data collection in specialized scientific experiments, one of the most notable being at the European Center for Particle Physics (CERN), the world's largest particle physics facility.

Implementation

HIPPI operates at the physical and data-link layers to provide connection-oriented communications between two points. HIPPI can operate at either 800 megabits per second (Mbps) or 1.6 gigabits per second (Gbps), and it has a simple flow control command set that can establish or tear down a connection in under a microsecond using a HIPPI switch. There is also a new standard called HIPPI-6400 that supports speeds up to 6.4 Gbps for distances up to 164 feet (50 meters) over twisted pair copper and up to 0.62 miles (1 kilometer) over fiber-optic cabling.

In its original format, HIPPI was a parallel transmission technology that used 50-pair shielded twisted-pair (STP) copper cabling for transmission of 800 Mbps over a distance of up to 82 feet (25 meters). Because longer parallel cables are impractical, a newer version called Serial HIPPI was developed in 1997 that encoded HIPPI's parallel bit stream into a single serial bit stream over fiber-optic cabling. For 800 Mbps transmission, the signaling rate is 1.2 Gbaud and two fibers are used, one for simplex transmission in each direction, giving full-duplex communications. For 1.6 Gbps transmission, four fibers are used. The maximum distances over which Serial HIPPI can operate are:

- 0.62 miles (1 kilometer) over multimode fiber
- 6.2 miles (10 kilometers) over single-mode fiber

Marketplace

Vendors of HIPPI equipment include Ascend, Cray Research, GigaLabs, Hewlett-Packard Company, IBM, and Silicon Graphics, Inc. (SGI). Products offered include adapter boards and interfaces, frame buffers, storage devices, tape servers, switches and routers, cables, and test equipment.

High-Speed Circuit Switched Data (HSCSD)

An interim upgrade for Global System for Mobile Communications (GSM) cellular communications systems.

Overview

High-Speed Circuit Switched Data (HSCSD) is the first upgrade available for GSM that boosts GSM's data-carrying capacity above its current maximum of 14.4 kilobits per second (Kbps). HSCSD is a pre-2.5G upgrade for GSM that has been deployed by a few carriers in lieu of General Packet Radio Service (GPRS), a 2.5G upgrade for GSM and other Time Division Multiple Access (TDMA) cellular systems that is just beginning to be widely deployed. Unlike GPRS, which requires that existing base station hardware be upgraded, HSCSD is a software-only upgrade and is easily implemented.

Implementation

HSCSD works by aggregating together groups of GSM time slots. Each GSM frame consists of eight time slots, each of which can provide up to 14.4 Kbps throughput for data transmission. HSCSD uses one slot for upstream communications and aggregates four slots for downstream communications. HSCSD is thus an asymmetrical data transmission technology that supports speeds of 14.4 Kbps upstream and 57.6 Kbps downstream. However, the overhead required by slot aggregation usually results in downstream bandwidth of only 28.8 Kbps instead of the theoretical 57.6 Kbps.

HSCSD supports two different transmission modes:

- **Transparent mode:** Offers a fixed bit rate for data transmission
- **Nontransparent mode:** Provides a variable bit rate

Prospects

HSCSD test deployments began in 1999. Some GSM operators that have upgraded their networks to HSCSD include Sonera in Finland and SingTel in Singapore. The majority of operators are upgrading directly to GPRS, however, and HSCSD is likely to be eclipsed quickly. This may be unfortunate, because HSCSD's circuit-switched transmission method has advantages over packet-switched GPRS in such applications as digital video, where low latency and guaranteed quality of service (QoS) are important.

High-Speed Serial Interface (HSSI)

A serial interface that supports speeds up to 52 megabits per second (Mbps).

Overview

High-Speed Serial Interface (HSSI) is defined by the standard EIA 612/613. HSSI supports serial transmission at speeds much higher than those supported by traditional serial interfaces such as RS-232 and V.35. At a top speed of 52 Mbps, HSSI is capable of supporting

- Synchronous Optical Network (SONET) transmission at 51.82 Mbps
- T3 lines at 45 Mbps
- E3 lines at 34 Mbps

Uses

HSSI is typically used to connect access servers and routers to T3 circuits for enterprise wide area network (WAN) connectivity. Top-end Cisco routers support HSSI through installable HSSI Interface Processor (HIP) cards that provide one HSSI port per router. HSSI is necessary for companies that want to deploy T3 WAN services such as DS-3 frame relay links because slower V.35 and RS-232 serial interfaces cannot operate at such speeds.

Notes

HSSI uses a 50-pin Centronics connector similar to a Small Computer System Interface (SCSI) connector, but you cannot use a SCSI cable to connect a HSSI router to a Data Service Unit (DSU)—you have to use a special HSSI cable instead.

High-Speed Token Ring (HSTR)

A high-speed version of Token Ring that never got off the ground.

Overview

High-Speed Token Ring (HSTR) was a development project of the High-Speed Token Ring Alliance, which consisted of Token Ring hardware vendors IBM, Olicom, and Madge Networks. HSTR was initially intended as a 100 megabits per second (Mbps) version of 802.5 Token Ring networking architecture that would provide a logical upgrade for existing 4 and 16 Mbps Token Ring networks. Speeds up to 1 gigabit per second (Gbps) were envisioned as being possible down the line.

Unfortunately, customer interest in HSTR waned with the rapid development of Fast Ethernet and Gigabit Ethernet (GbE) technologies, and in 1998 IBM withdrew from the alliance and the effort collapsed. The effective result is that Ethernet has finally won the local area network (LAN) wars with Token Ring and Fiber Distributed Data Interface (FDDI) networking architectures, and these two architectures are now considered legacy technologies that have no real future.

HiperLAN/2

An emerging high-speed wireless networking standard.

Overview

HiperLAN/2 is a global standard for broadband wireless networking developed by the Broadband Radio Access Networks (BRAN) group of the European Telecommunications Standards Institute (ETSI). HiperLAN/2 is designed to be an extension of Asynchronous Transfer

Mode (ATM) technology to the wireless networking arena and is expected to be ratified as a standard sometime in 2002. HiperLAN/2 is an alternative to the existing 802.11a high-speed wireless networking standard developed by the Institute of Electrical and Electronics Engineers (IEEE) and is intended as a worldwide wireless networking platform that is interoperable with ATM, third-generation (3G) cellular systems, and 1394 (Firewire) systems.

Adoption of HiperLAN/2 standards is being driven by the HiperLAN2 Global Forum (H2GF), an open industry forum launched in 1999 and whose founding members were Bosch, Dell Computer Corporation, Ericsson, Nokia, Telia, and Texas Instruments. Two other HiperLAN standards being promoted include

- **HiperAccess:** A standard for fixed outdoor use and for providing access to wireline networks
- **HiperLink:** A standard for building indoor radio backbones

Architecture

HiperLAN/2 provides raw data transfer speeds of up to 54 megabits per second (Mbps), which corresponds to roughly 20 Mbps actual sustained throughput. Instead of operating in the slower, crowded 2.5 gigahertz (GHz) Industrial, Scientific, and Medical (ISM) frequency band, HiperLAN/2 uses the higher 5 GHz frequency band for greater throughput. Actual frequencies used depend on the country in which the technology is deployed, for example:

- **United States:** 5.15–5.35 and 5.725–5.825 GHz
- **Europe:** 5.15–5.35 and 5.470–5.725 GHz
- **Japan:** 5.15–5.35 GHz currently proposed for an alternate standard similar to HiperLAN/2
